HISTORY AND ANALYSIS OF THE METHODS OF RESUSCITATION.

WITH A DESCRIPTION AND A DISCUSSION OF THE AUTHOR'S PHARYNGEAL INSUFFLATION APPARATUS FOR ARTIFICIAL RESPIRATION IN MAN.

By S. J. MELTZER, M.D., LL.D.,
NEW YORK.
(From the Department of Physiology and Pharmacology of the Rockefeller Institute for Medical Research.)

I. Historical Review.—It is quite probable that from time immemorial men tried to revive the apparently dead, and that for accomplishing this end employed all sorts of procedures; but our actual knowledge of these procedures does not reach very far back. The verifiable history of resuscitation is only about 150 years old. The society which was organized for this purpose in Amsterdam, 1767, seems to have made the first attempt to lay down definite rules for resuscitating the apparently dead; at least it was the first attempt which left a record. The rules were embodied in a little book which was translated in 1773 by a Dr. Cogan into English. That booklet stimulated the public spirited Dr. William Hawes to establish in London an organization under the name of The Humane Society, which had in view an object similar to that of the Amsterdam Society, and which is still in existence under the name of The Royal Humane Society. At the time when The Humane Society was established, England was fortunate to possess many illustrious medical men, some of whom took an active interest in the development of the subject of resuscitation. I need only mention such medical stars as John Hunter, who was a director of that society; his brother William Hunter, Cullen, Monro secundus, and Fothergill. It should be mentioned that de Haën published in 1772 results of an "experimental inquiry into the phenomenon of drowning and resuscitation as seen in dogs." De Haën was then professor of medicine in Vienna. But he came from Holland, was a pupil of Boerhaave, and it was probably the apparently dead from drowning in Dutch waters, and not in the waters of the Danube River, which made him look experimentally for developing methods of resuscitation. It was again then Holland which gave the stimulus to experimental studies of life-saving methods. At any rate, it was in the eighth decade of the eighteenth century that procedures of resuscitation assumed a scientific aspect, began to be systematized, became a medical subject, and found a permanent place in the medical literature.

The latter fact is in a great measure due to the activities of The Royal Humane Society, which from the start kept records of all cases of attempted resuscitation which came to its knowledge. At various intervals it formulated and published rules, in conformity with the views which prevailed at the time, and stimulated individuals to and formed committees for special investigations with the object of discovering reliable methods to be employed. In several interesting papers, Arthur Keith[1] made us acquainted with some historical data and with the details contained in the records of the society. At the time the mentioned societies were founded the subjects to be resuscitated were chiefly those apparently dead from drowning; hence, the special interest which Holland and England took in the matter. However, the progress made since this time in industry, science, and medicine created new victims in its train. The introduction of gas for the purpose of lighting and heating, the extensive development of mining, of the knowledge and the technical application of electricity, the discovery of ether, chloroform, and other anesthetics, the growth of the domains of surgery, the discovery and popularization of narcotic drugs; all these blessings multiplied greatly the unfortunate opportunities for the necessity of employing methods of resuscitation.

Did the methods improve with the growth in the necessities of their application? I shall try to answer by giving a brief outline of the history of resuscitation which may be justifiably divided into two periods, the year 1856 being the dividing line. In the last 60 years resuscitation consisted and still consists practically exclusively in the application of artificial respiration in one form or another. During the first period, however, besides artificial respiration many other procedures were employed which may be collectively described as stimulations. The earliest procedures consisted in the application of heat to the body, of various stimulants to the skin, the nose, etc., in blood-letting, in the production of vomiting "by the French method." An interesting procedure was that of "fumigation"; it consisted in filling the large bowel with tobacco smoke. "For nearly 40 years great importance has been attached to this curious procedure. The record of case after case bears witness to the success ascribed to this method." The disappearance of fumigation from the list of permissible means of resuscitation is characteristic for the "ups and downs" in the history of therapeutics in general. Benjamin Brody found in three experiments that the infusion of 4 ounces of tobacco, administered per rectum, would kill a dog, and one ounce a cat. The Royal Humane Society became alarmed and relegated fumigation

to the list of forbidden rules (Keith). The use of artificial respiration as a method of resuscitation had rather a variable fate during this period. Aside from the barrel method (rolling those apparently dead from drowning on a barrel), artificial respiration was performed by inflation of the lung from mouth to mouth while the nose of the victim was kept closed, a method which seemed to have been long in practice in reviving the still-born and which, in this domain, is occasionally still in use. However, about 1776, the bellows method came to the front. John Hunter constructed double chambered bellows, one chamber being used for filling the lungs and the other chamber for suction.* Hunter recommended the use of oxygen for inflation—discovered only two years previously by Priestly. Monro secundus also constructed a double-chambered apparatus; his bellows, however, were too large; the chambers had a capacity of 1500 cubic centimeters. The bellows, which were later accepted by The Royal Humane Society, were designed by Charles Kyte and had a capacity of only 500 cubic centimeters. The nozzle of the tube connected with the bellows was introduced into one nostril while the other nostril, as well as the mouth, were kept closed, and the cricoid was lightly pressed backwards to prevent the insufflated air from passing down into the esophagus. Goodwin discovered that in the apparently dead the tongue falls backwards; the insufflation of air might therefore rather assist in occluding the entrance into the larynx by pressing down the tongue upon the epiglottis. Monro overcame this difficulty "by passing the catheter into the larynx by way of the mouth."† "From 1782 onwards bellows were recommend by The Royal Humane Society as the best means for artificial respiration. . . . For 40 years no one had a word to say against them; they were used in every country." However, in the twenties of the nineteenth century Benjamin Brody began to maintain that artificial respiration was only a secondary means in the resuscitation of the apparently dead, and in 1829 Leroy d'Etiolles stated in a memoir that it was possible to kill an animal by suddenly inflating its lungs. "Leroy's experiments alarmed The Royal Humane Society . . . the bellows fell into disgrace and in 1837 it disappeared from the list of methods recommended by the society." Keith tells us that "during the period in which artificial respiration was in abeyance the chief treatment lay in the application of warmth, treatment commencing with the immersion of a patient in a bath at about 100° F." The following data, taken from one of Keith's tables, present us with a bewildering illustration. From 1795 to 1811, when warmth and inflation (bellows) were used, there were as may as 54.8 per cent. unsuccessful cases; from 1832 to 1851, when warmth and friction were used, there were only 10 per cent. unsuccessful cases. Is this striking contrast merely an outcome of the familiar unreliableness of information derived from statistical data, or is it due to the fact that inflation of the lungs by bellows is indeed a very dangerous procedure?

As stated above, the year 1856 introduced the second period in the history of resuscitation. In contrast to the foregoing decades, artificial respiration became practically the only method of resuscitation. However, the character of the artificial respiration practised nearly exclusively in the greatest part of the second period, assumed a different aspect. While in the first period inspirations were produced by *inflation*, in the new methods of artificial respiration, the inspiration was accomplished by *aspiration*, and the procedures, which are expected to bring about artificial respiration, consisted in manual handling of the victim. These methods of artificial respiration possess the undoubted advantage that no special apparatus are required for their performance, and that the manipulations can be started immediately on discovery of the victim. Some sort of movements of the chest and abdomen were undoubtedly practised ever since attempts of resuscitation were made. But the movements we are speaking of here are of an orderly, systematic character, based upon more or less well founded scientific observations.

These movements may be divided into three classes: 1. Movements which produce originally active expiration, while the inspiration is accomplished passively. 2. Movements which actively produce inspiration, while the expiration is accomplished passively. 3. Active movements producing the inspiration as well as the expiration. This last mode of respiration was the first new form which was introduced in 1856 by the celebrated physiologist Marshall Hall and which was termed by him the "postural method." The subject was first placed in the prone position and pressed upon the back, causing thereby an active expiration; it was then turned over on the side and the shoulder was raised, which brings about an active inspiration. Soon after Hall's communication was made, Sylvester introduced the method which is now known by his name. The subject is kept in the supine position and both arms are strongly raised above the head, thus stretching the pectoral muscles and causing hereby an active inspiration. The expiration is accomplished passively by returning the arms to the side of the subject. This method was recommended by the first Committee on Resuscitation appointed by The Royal Humane Society in 1861, and it is still largely in use in many parts of the world. In Germany it was adopted with a modification by Frosch: instead of returning the arms to the side of the patient, they are pressed on the cartilaginous part of the thoracic ribs, causing hereby some degree of active expiration. I wish to add that the last-mentioned procedure may possibly have the further advantage *that it is capable of producing some stimulation of the heart.* By the antagonists of the Sylvester method, it is accused that in some instances it has caused fracture of the ribs and even rupture of the liver. About 1871, Howard, a police surgeon of New York, suggested another method, namely, to place the subject in the supine posture, supported by a pillow, to apply the palms of the hands on the prominent parts under the subcostal margins, and to force the abdominal contents upward; thus pro-

*The invention of an apparatus for artificial respiration in which the inspiration is accomplished by insufflation and the expiration by suction has been in recent years usually ascribed to the noted Viennese pharmacologist, H. H. Meyer. As we see, this form of apparatus was invented and used by John Hunter at least 140 years before. See Keith[1].

† More than a hundred years later we find in the medical literature several living writers claiming priority for the inventon of this procedure.

ducing active expiration. The inspiration is produced passively by the recoil of the ribs and the return of the abdominal contents to their original place. The method did not find favor, and it even has been alleged that rupture of the liver is apt to follow a too vigorous use of the Howard method.

In 1899 the Royal Medical and Chirurgical Society instituted its fourth committee. "Professor E. A. Schäfer was a member, but ultimately became the committee, and his report, read in 1903, is one of the most important contributions ever made to the literature of resuscitation" (Keith). The method which he recommended is now known by his name or as the "prone method." The subject is placed face downwards, the chest resting directly on the floor. The operator kneels astride the prone subject and places his hands over the lower ribs and the lumbar parts on each side of the spine. To produce the expiratory movement the operator, keeping his arms outstretched, brings the weight of his body on the lower dorsal region of the patient; the abdominal viscera are hereby powerfully compressed and forced against the diaphragm and lungs, which are thus brought into a position of ultra expiration. The recoil which occurs when the operator's weight is withdrawn causes an inspiration. In principle Schäfer's method is identical with that of Howard, except that it is easier to perform and has the important advantage that, the subject being in a prone position, the tongue falls forward and thus does not interfere with the entrance of air into the larynx.*

Some eight years ago a committee appointed by The Royal Society of Medicine recommended Schäfer's method in preference to that of Marshall Hall or Sylvester. Nevertheless, The Royal Society and other life-saving associations still give, I believe, preference to the Sylvester method.

In the United States two commissions† investigated the methods of resuscitation. Both came to the conclusion that Schäfer's method is preferable to that of Sylvester.

Before mentioning other methods of artificial respiration employed in the last two or three decades in resuscitation, I wish to refer here to Laborde's method of traction of the tongue, although it can hardly be considered as a method of artificial respiration. There is no doubt that in some instances, especially in accidents from anesthesia, a few tractions of the tongue may reestablish respiration. It is evident that in most of these cases the aid is rendered by lifting the epiglottis away from the entrance into the larynx. However, it is not this effect which Laborde had in mind. He states that he succeeded by his method in resuscitating from drowning even after there was no respiration for one hour. Laborde believes that the favorable effect is due to reflex action through the glossopharyngeal and other nerves. Soon after Laborde's communication there were some favorable reports from the use of this method, especially in France. However, in recent years I have not come across any mention of this method in the medical literature.

Besides the previously mentioned manual methods in the last three decades a goodly number of procedures were proposed, and partly came into use, which collectively may be designated as mechanical methods of artificial respiration. Fell (1887)[1] was probably the first one to use successfully in human beings (in cases of poisoning) the method usually employed in the physiological laboratories (tracheotomy and bellows). Later Fell recommended the use of a mask in place of a tracheotomy tube. Northrup (1896)[2] advocated the use of a modified O'Dwyer tube connected with bellows (Fell-O'Dwyer apparatus). At about the same time several French investigators attempted to devise methods of artificial respiration by the aid of mechanical means, among whom Tuffier and Hallion, and Doyen deserve to be especially mentioned. Doyen's apparatus consisted of "duplex" bellows (for insufflation and suction) attached to an intralaryngeal cannula. R. Matas (1902)[3] constructed an apparatus in which a modified O'Dwyer tube was connected with an automatically acting pump. The pump contained originally two independent metal cylinders for inspiration and aspiration. However, the first experiment made on a dog convinced Matas that the suction force, exercised by the aspirating cylinder, does damage to the lungs, and he eliminated that part from his apparatus.* In his efforts to apply the method of intubation to all cavities and tubes of the body Franz Kuhn became also active (in Germany) in introducing the method of intralaryngeal intubation as a means of resuscitation.

To the foregoing the statement is to be added that, as is generally known, in the last seven or eight years various efforts have been made in this country to introduce mechanical resuscitating machines. But I wish to point out that most of these efforts are to be distinguished from all foregoing activities by one deplorable characteristic: while the activities in the foregoing periods were stimulated practically solely by humanitarian and scientific purposes, nearly all the apparatus and machines which are being introduced at present, and which receive a lesser or greater unscientific publicity, have one unpleasant feature in common, namely, the plain and unveiled commercialism which is evidently the

*Several years ago in a conversation which we had in London, Professor Schäfer remarked that "if he were now confrnoted with the task of resuscitation he would kneel astride over the subject and perform the simple motions of horseback riding without employing his hands and arms at all."

† On the first commission Drs. Cannon, Crile, Yandell Henderson, and Meltzer represented the American Medical Association; Dr. Spitzka and Mr. Elgin represented the National Electric Light Association, and Drs. Kennelly and Elihu Thomson represented the General Electric Company. Dr. Cannon was elected chairman and Mr. W. D. Weaver, then editor of the *Electrical World*, was elected secretary of the commission. Mr. Elgin, past president of the National Electric Light Association, deserves special credit for the creation and success of this committee. The second commission was appointed by the Bureau of Mines of the Department of the Interior and consisted of Drs. Cannon, Crile, Erlanger, Henderson, and Meltzer; the report of this commission is known as "Technical Paper No. 77."

*Courtois seems to have been the first one who as early as 1790 (*Jour. de med., chir. et pharm.*, Paris, LXXXII, p. 361) introduced the duplex metal cylinder as a means of inducing artificial respiration under the designation of "pompe apodpinque" (quoted from a pamphlet by Dr. William Harrison, Pneumatry papers No. 1, Detroit, Mich., 1916). According to Harrison, Poe's Artificial Respirator, which is now extensively advertised by the Life Saving Devices Company under the name Lungmotor, is identical with Courtois' "pompe apodpinque." Harrison himself is now introducing an apparatus under the name of "Pneumatizer" which, according to the inventor, is free from the shortcomings of the Lungmotor.

sole motive for their construction. Their introduction to the public is accomplished by the usual methods by which commercial products try to make headway, namely, by a more or less loud advertising. It is rather a sad chapter in the history of resuscitation; but I do not intend to dwell upon its details.

II. *Criteria for the Efficiency of the Methods of Treatment.*—What evidence do we possess that certain methods which are employed for resuscitation are really efficient? As far as I know there are at present only three criteria which may serve as guides for our judgment.

Statistics. For more than 100 years the character of the evidence was exclusively of a statistical nature, namely, that if a certain method, employed for resuscitation, had a high percentage of successes to its credit, it was considered as a proof that the method was indeed a useful one. But the statistics given in the above mentioned articles of Keith demonstrate at a glance the fallacies contained in this method. For instance, for many years "fumigation" (introduction of tobacco into the large bowel) seemed to be a most reliable method. Later, however, on the contrary, it was forbidden. At another period when only warmth and friction were employed for resuscitation, these procedures, judging from the statistical data, seemed to have given the best results. Then the various methods of artificial respiration had, as seen above, their "ups and downs" in the history of resuscitation. It is evident that the value of the reports of successful treatment of the apparently dead varied greatly with the character and judgment of the reporters and with the nature of a great many circumstances which were not taken into consideration. Uncritical, statistical data, as is now generally conceded, have not only no value, but are very often decidedly misleading. As to the statistical data collected for transparently unlaudable purposes, with which regrettably all branches of medicine in our country is overwhelmed, the term "misleading" is surely insufficient for their characterization.

Respiratory Volume.—"Science is measurement." quotes Schäfer in his Harvey Lecture.[5] The criterion which played and still plays a considerable rôle in the estimation of the value of the methods of manual artificial respiration consists in measuring the volume of the air inspired and expired into a spirometer. This method was, I believe, introduced by Schäfer. At first he experimented on drowned dogs; but these experiments gave no satisfactory results, because drowned dogs recover often without artificial respiration, sometimes even after having been for five minutes under water, that is, without any respiration whatsoever. On the other hand, if the heart of drowned animals stops beating, as a rule none of the manual methods of artificial respiration, no matter how early begun, is capable of resuscitating them. The experiments with measuring the volume of air on dead human bodies also gave no satisfactory results on account of the various degrees of rigidity of the thorax. The most appropriate way of testing the manual methods of artificial respiration seemed to be to study the volume of inspired and expired air of living conscious human beings. By using this method Schäfer found that his prone method of artificial respiration gave a much larger volume than the supine or Sylvester method. However, it was soon discovered that the normal individual interferes involuntarily with the inspiration and expiration either by partly closing the glottis and thus reducing the amount of the expiratory and inspiratory air, or the volume of the respiratory air is influenced by the unconscious innervation of the respiratory muscles. Ploman[6] carried out his studies on human beings who were previously trained not to participate in the respiration during the execution of any of the methods of artificial respiration. According to him, Schäfer's method gives definitely smaller volumina of respired air than the method of Sylvester and its modifications. It seemed, however, that even a previous training was not a sufficient guarantee that the individuals experimented upon do not interfere sometimes unconsciously with the course of the artificial respiration. Lilijenstrand, Wollin, and Nilsson[7] tried to overcome the difficulties by studying the effect of artificial respiration on conscious *apneic* individuals. The apnea was brought on by a small series of deep respirations, and it is generally assumed that during a state of apnea the individual is completely relaxed and has no desire for breathing. According to these authors the respired air volumina obtained under any of the manual methods of artificial respiration are much smaller than any normal respirations, but they agree with Ploman that Schäfer's method gives a still smaller volume. Loewy, one of the most active investigators in this line came out,[8] however, with the claim, based upon experimental studies, that during apnea the individual is not completely relaxed, but, on the contrary, the respiratory muscles are in a state of tonus, which may mean that in this state the individual is rather more ready to react to the stimulations produced by artificial respiration.

As mentioned before, the apnea produced in the experiments of Lilijenstrand, Wollin, and Nilsson, and probably also in those of Loewy, were brought on by a small series of respirations. Yandell Henderson[9] undertook a critical examination of Schäfer's and other methods of artificial respiration on students "who experienced after overventilating their lungs by two or three minutes of voluntary forced respiration a lack of desire to breathe (apnea), lasting from 40 to 80 seconds." He found that under these circumstances Schäfer's method gives a slightly larger volume than that of Sylvester, especially when Schäfer's method is carried out with "the arms stretched forward." But even in Henderson's investigations the respiratory volumina obtained under artificial respiration were about one-half or less than the one obtained in normal respirations.

However, no matter to which of the various claims greater weight is to be attached, it seems quite evident that the method of measuring the volumina of inspired and expired air is incapable of demonstrating that any of these methods is in a position to keep up the respiration for any length of time when the respiratory mechanism is in a state of complete failure. It seems that in the end it is not the experimental method of measuring the volumina of the respiratory air which influences the contending parties to take sides with one or the other method; it is again essentially the old method of making claims by statistical data which induces the fol-

lowers of various methods to consider one or the other method of manual artificial respiration as the more efficient procedure to employ in resuscitation of the apparent dead.

Curarized Animals.—Several years ago the writer[10] introduced a new method of testing whether a certain procedure of artificial respiration is indeed capable of keeping an individual with complete failure of the normal respiratory mechanism interminably, or at least for many hours, alive. The essential factor in this method consists in keeping the respiratory muscles of the animal completely paralyzed by means of curare for as many hours as we wish to continue our experiment. The animals are at the same time anesthetized by ether, administered by means of the method of artificial respiration which is undergoing the test. When the method of artificial respiration is inefficient the circulation comes sooner or later to a complete standstill. When, however, the method is efficient the circulation can be kept practically in a uniformly normal state for many hours, although the animal remains completely paralyzed. At the end of such a successful experiment spontaneous respiration can frequently be restored to normal by means of an injection of physostigmin.

By means of this method my procedure for artificial respiration, which I am going to describe later, has been tested on hundreds of animals. By the same method I have tested the efficiency of the Sylvester method, of the Schäfer method, and of the pulmotor which was so much in vogue at that time. Regarding the manual methods my statements can be brief, and are as follows: The longest time the circulation of a curarized and anesthetized animal could be kept up by the Sylvester method was twelve minutes, even when the tongue was kept pulled out by means of a forceps. The experiments were made on dogs. By the Schäfer method, with the anterior extremities stretched forward, the shortest period during which the circulation was kept on going amounted to about eighteen minutes. The longest period (one dog) lasted thirty-one minutes. In this dog the manipulations were carried on with great energy, and at the autopsy it was found that the liver was ruptured.

The efficiency of the pulmotor, which was loaned to us by the Bureau of Mines, I have investigated on a large number of dogs and the results deserve a more extensive statement. The pulmotor was applied by means of a mask fitted specifically for each dog; the tongue was kept withdrawn. In some instances the trachea was connected with a manometer to establish the pressures during inspiration and expiration. In some instances the thorax was split transversely and the condition of the lungs and the heart was established by ocular observation. The external part of the pulmotor consists of an ingenious mechanism which provides automatically for inspiration and expiration. The apparatus is driven by the force of a specifically adopted oxygen tank. However, according to Haldane and Henderson's analysis of the air-oxygen mixture delivered by it, it showed only 26.75 per cent. oxygen.[9] The experimental results were strikingly disappointing. In my experiments out of a large number of dogs the circulation of only one could be maintained for one hour. The balance of the experimental animals died sooner or later. In these animals the circulation stopped when they were left exclusively to the effects of the pulmotor. The manometer connected with the trachea showed, as a rule, a comparatively small pressure, the utmost 40 millimeters of water. When the thorax was kept open it was observed that practically without exception with the continuation of the use of the pulmotor the size of the lungs became gradually smaller and smaller. This could also be observed in young animals with normal thorax. When the pulmotor had been used for some time, the lungs, in many cases, presented an uneven appearance—small collapsed areas alternating with emphysematous ones. It seems that in general our experience agreed with the experience of Matas when he used an apparatus with separate chambers for inflation and suction. The success with the pulmotor was more satisfactory when it was connected directly with the trachea by means of a tracheotomy tube. The inefficiency of the pulmotor seems to be caused essentially by two elements. The first element is its automatic arrangement. While the air-oxygen passes from the nasopharynx into the trachea it seems to meet with some sort of obstacle which converts prematurely the inspiratory movement into an expiratory one. The result is an insufficient exchange of respiratory gases. The second deleterious element is the suction; an element inherent to other machines on the market. Apparently in many cases the suction closes most of the bronchioles before it succeeds in removing deleterious expiratory gases from the alveoli. In these instances the air within the dead space is caused to move, which simulates respiratory movements without producing an actual exchange of gases. As stated before, my experience in the experiments with the pulmotor (which in one case has been witnessed by Drs. Cannon and Henderson) coincides with that of Matas. In a recent paper by Yandell Henderson" he states that he is inclined to doubt "whether an active withdrawal of air with a pump of limited stroke has any very serious objections" and refers to his experiments "with two pumps arranged in a manner similar to the 'lungmotor' and worked quite violently"; he observed "no particular ill-effects of the lungs." Without entering into a discussion of the nature of Henderson's experiments which do not permit a comparison with the activities of the pulmotor and lungmotor, it is sufficient to recall the fact that in the experiments of Henderson the pumps were connected directly with the trachea, a condition which, as mentioned above, increases the value of the pulmotor.

III. *The Author's Method of Pharyngeal Insufflation.*—The most reliable method of artificial respiration is, in the author's opinion, the method of intratracheal insufflation introduced about seven years ago by Dr. Auer and the writer. The writer has kept many animals for more than 24 hours continually under ether administered by the method of intratracheal insufflation without causing any injury to them. Furthermore, in several cases of poisoned human beings without any respiration, intratracheal insufflation was kept up for more than 15 hours until the patients recovered. However, the introduction of the tube into the trachea requires some dexterity and practice, and any of the apparatus now on the market used for keeping up the

intratracheal (or as it is now called by some writers, endotracheal) insufflation is usually expensive. It is therefore highly improbable that in most emergency cases an apparatus for intratracheal insufflation as well as an expert surgeon who knows how to introduce the tube and how to handle the apparatus will be just at hand. When I was made chairman of the subcommittee of the above-mentioned commissions to study the problem of artificial respiration by means of apparatus I developed the method of pharyngeal insufflation which worked infallibly in hundreds of cases of animals under the influence of curare and ether.[12] Later, when I attempted to use such an apparatus on dead human bodies I found that the method had to undergo some changes in order to be adaptable to the human being.[13] Since the last publication I have made some advantageous changes in this apparatus and had several opportunities to test the efficiency of the apparatus in its present form on living human beings with completely paralyzed respiration. In the following I

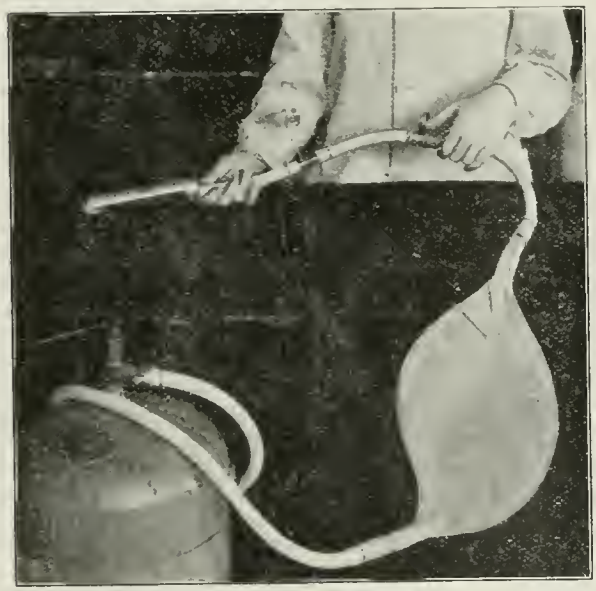

FIG. 1.—Showing an oxygen tank, the interpolated rubber bag, the respiratory valve in an inspiratory position, the T-tube, and the pharyngeal tube.

am going to describe the apparatus, its principles, and the procedure of its application.

From the data reported in the historical part it can be seen that the idea of producing artificial respiration by means of a pharyngeal or laryngeal tube conconnected with bellows is not new. Neither are the ideas new that too much pressure of the air insufflated into the lungs may do harm or that a good part of the insufflated air may enter into the stomach and the intestines. However, when I started developing my apparatus I was not yet familiar with these data. When I began to use a pharyngeal tube for artificial respiration I was confronted with several difficulties: the insufflated air is liable to escape through the nose or backward through the mouth, or the air may enter chiefly into the stomach and from there into the intestines and do more harm than good; at any rate, perhaps only little of the insufflated air will enter the lungs and may be insufficient to produce a satisfactory respiration. In the last published article[13] I described devices which should meet these difficulties; I shall discuss them again in this paper. Another serious obstacle to the use of pharyngeal insufflation was the possibility of driving air into the lungs under too much pressure so that it may injure these organs. To meet this possible danger I suggested the interpolation of a mercurial valve into the tube which connects the respiratory valve with the foot bellows, the mercurial valve being arranged for about 20 millimeters pressure. This mercurial valve, however, was found to be, for reasons which I do not need to discuss here, a cumbersome and undesirable device. Another unsatisfactory condition seemed to come from the direct connection of the bellows with the respiratory valve; the air from the foot bellows is practically not continuous and the inspiration develops only gradually to the desirable pressure. On acount of these defects two advantageous changes were introduced in the present apparatus, the entire details of which I am now going to describe.

First, *the foot bellows;* they need no special description. It is hardly necessary to state that the required inspiratory pressure could be obtained either from an oxygen tank or from a tube coming from a constant pressure somewhere in the hospital or other building. The bellows are merely recommended on account of their comparative cheapness and the convenience with which they can be transported to any place where they may be needed. Second, *the respiratory valve.* It is a small tube which may be conveniently kept in the hand when using it; the tube has a protruding movable ring into which the thumb fits. When the thumb moves the ring to the right side the driven air or oxygen pass through the respiratory valve, and, as will be seen later, pass further into the pharynx and into the lungs. When the ring is moved to the left side the escape from the respiratory valve is prevented and the air or oxygen accumulate meanwhile in the large bag interpolated between the source of pressure and the respiratory valve, while an aperture appears above the ring for the escape of the expiratory air from the lungs. (See Fig. 1.) In the tubing connecting the bellows with the respiratory valve a large rubber bag is interpolated. The presence of the bag offers the advantage that during the expiratory phase the air or oxygen may accumulate in that bag and be ready for a full inspiratory blast as soon as the thumb moves the ring to the right side. Third, *the pharyngeal tube.* This tube has a flat surface at its lower side which rests on the tongue and a curved surface on its upper side. At the pharyngeal end of the tube the upper surface is longer than the lower one. The external end of the tube has a protrusion with a neck for connection with the respiratory valve and an opening through which a stomach tube may be pushed down through the esophagus into the stomach. When no tube is in use this opening is closed with a movable plate. (See Fig. 2.) Fourth, a *T-tube* which is interpolated between the respiratory valve and the pharyngeal tube. The T-tube carries on its rubber end a clamp screw, which, when not screwed down, permits most of the air to escape through the tube, while, on the other hand, by *gradually* screwing down the clamp upon the rubber tube the amount of air entering the pharyngeal tube will gradually increase. (See Figs. 1 and

3.) This T-tube arrangement supplants, as it will be shown later, the mercury valve of the earlier form of apparatus and is used with great advantage for the same purpose, namely, to prevent the harm of an excessive pressure. Fifth, *a padded wooden*

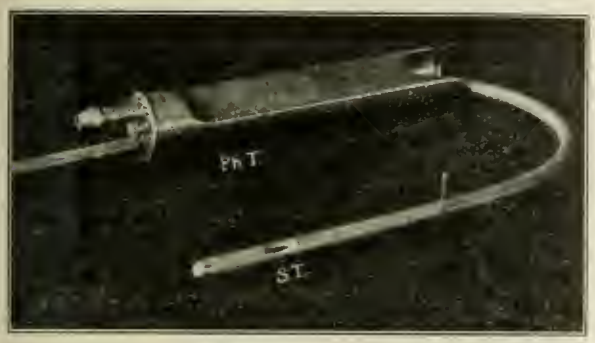

Fig. 2.—Showing an enlarged pharyngeal tube (Ph.T.) with its various particulars, and a stomach tube (S.T.) in it.

board, to be used for compressing the abdomen by means of belts. (See Fig. 4.)

The rubber tubing used in this apparatus must have thick walls, so that it should not kink; metal and no glass tubes ought to be used for all other connections—they should not break when the apparatus is used in a great hurry and without special care. All these parts *ought to be kept connected and kept in readiness* in a handy small bag. In addition to the described apparatus the bag ought to contain, (1) a stomach tube which fits into the external opening of the pharyngeal tube; (2) an appropriate tongue forceps; (3) a roll of tape, and (4) a pair of scissors. Bellows, rubber tubing, etc., should be frequently examined for their efficient activity, in order that the apparatus should not fail when its application is needed in an emergency.*

When coming to a victim who requires immediate artificial respiration the order of the procedure should be as follows: First the application of the abdominal board—in order to prevent the entrance of the insufflated air into the stomach and the intestines. Second, to pull out the tongue as far as possible by means of the forceps. Third, to insert the pharyngeal tube of the readily connected apparatus as deep into the pharynx as possible with the flat side of the tube on the tongue. The tongue should now be tied to the tube by means of tape—not too tight. The tying of the tongue has two purposes: (1) It prevents the falling back of the posterior end of the tongue and of the glottis, and (2) it keeps the pharyngeal tube in place. The working of the bellows with one foot, and the moving of the ring of the respiratory valve with the thumb of the right hand should be started immediately on tying the tongue to the pharyngeal tube. At the beginning of the procedure the T-tube should be kept open; it should soon be gradually screwed down until the thorax shows a distinct raising when turning the ring to the right and falling, when turning to the left. The heaving of the chest need not be too strong. The degree of the heaving can be readily controlled by means of the screw, which should be turned down gradually, and which will then be capable of accomplishing all the care which may be obtained from the use of a mercurial valve. Moving of the ring thirteen to fifteen times per minute will give a satisfactory respiration; or the operator may time the moving of the thumb by the rhythm of his own respirations. In case of need one individual who had some training may accomplish all three procedures and start the artificial respiration in less than one minute after finding the victim.

Should the respiratory failure take place while the abdomen is open, a condition in which the abdominal board cannot be applied, the plate at the outer end of the pharyngeal tube should be opened and the stomach tube pushed through the opening into the stomach: any surplus of air which may enter into the stomach will thus promptly escape through the stomach tube. This device has been tested on many paralyzed animals and it was found thoroughly capable of properly supporting the function of respiration. The insertion of the stomach tube may be used even where the abdominal board is being applied; in fact, it may be saving time by introducing the stomach tube immediately on inserting the pharyngeal tube; the application of the abdominal board may be carried out later with greater leisure. On the other hand, the application of the abdominal board has the further advantage that it drives a part of the blood contained in the splanchnic region into the heart and thus supports

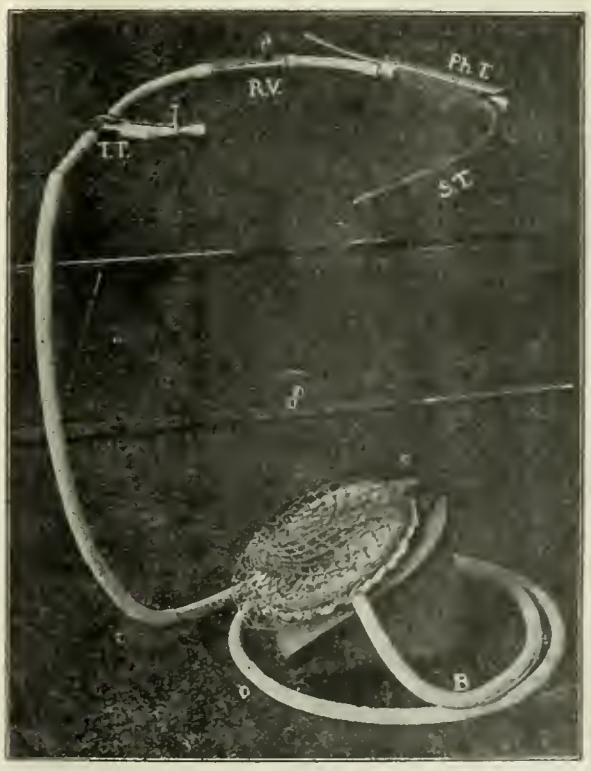

Fig. 3.—Showing an earlier arrangement of the apparatus. B, bellows; T.T. T-tube inserted between the bellows and the respiratory valves; R.V., respiratory valve; Ph.T., pharyngeal tube; S.T., stomach tube.

to a degree the failing circulation. (See Fig. 1 in my previous article.[2])

The size of the pharyngeal tube which goes with the apparatus is generally sufficient to prevent too much of an escape of the insufflated air through the

*The apparatus ("Meltzer's pharyngeal insufflation apparatus" for artificial respiration in cases of emergency in man) can be obtained from George Tiemann & Co., 107 Park Row, New York City. It is not patented. Its cost is probably less than one-fifth of the patented apparatuses.

mouth; furthermore, the prolongation of the curved side of the tube raises the soft palate and thus prevents the escape of air through the nose. However, we need not care about slight escapes of air, since the amount of insufflated air can be easily controlled by means of the T-tube and the clamp screw. In my experience, which extends to many hundreds of animals and a few human beings, a single trained individual is capable of working the bellows with one foot and using the respiratory valve with one hand, while the other hand controls the insufflated pressure by means of the T-tube. On various occasions (at the Army Medical School, Washington, at the Johns Hopkins Medical School, in various hospitals, etc.) this method of artificial respiration was demonstrated on curarized animals with the thorax wide open, the administration lasting, as a rule, for several hours. The pharyngeal tube was often removed for a long time, so that the heart practically stopped beating, and it then took only a very short time to start the artificial respiration and bring the heart to its previous normal beat. *At least in four instances the respiration was in complete abeyance in human beings for ten minutes or longer while the here described apparatus kept the heart going at a*

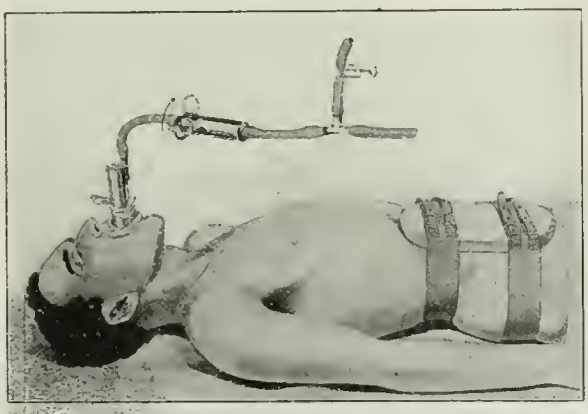

Fig. 4.—Showing the apparatus in position, except the bellows and an oxygen tank.

*normal rate and the entire circulation in good condition.**

I wish, however, to state expressly that our test by which we gauge the value of apparatus or of manual methods of artificial respiration is a severe one. It presupposes that we always have to deal with victims whose respiratory mechanism is completely paralyzed and cannot be reached by any reflex stimulation. But there can be no doubt that the vitality of the nervous system of many victims, although they actually show no respiration, is not yet completely abolished and may therefore still be capable of recuperating sooner or later and of responding to some stimulation. In such cases even methods of artificial respiration of moderate efficiency may sometimes be capable of sustaining the life of the individual for a certain period, at least, until an efficient apparatus is procured. Furthermore surely there are cases in which the application for a few minutes only of even inefficient apparatus or methods may support the failing respiratory mechanism and thus help to restore the life of the victim. It is therefore proper to advise that in the absence of reliable and efficient apparatus for artificial respiration any type which is just at hand ought to be used—provided the apparatus does not possess the two above-mentioned dangerous elements, namely, *the automatically regulating inspiration and expiration and the special provision for expiration by means of suction.*

However, it is rather probable that in most instances no kind of apparatus for artificial respiration will be at hand when an accident has happened. It ought therefore to be the rule that in each and every case a *manual* method of artificial respiration must be instituted immediately on discovery of an individual who shows no spontaneous respiration. As we have seen above, both methods which are now in vogue, namely, that of Sylvester and of Schäfer, may prolong, to some degree, the life of curarized animals. On the other hand, it was found that the life of curarized animals was sustained longer by using the Schäfer method than by the method of Sylvester. But we must keep in mind that all these methods, simple as they may appear, require some experience for their proper execution. I shall therefore suggest that in rendering first-aid to accident cases the method of immediate choice should be the one for which there is an operator present who possesses special experience in just that method. In other words, the Sylvester method should be given the preference if the men who are to render the first-aid are more experienced in this method than in that of Schäfer; one is capable of rendering better aid with a method with which he is familiar than with one which he has never used before. However, I shall here go on record, as I did before in the report of the mentioned commissions, that *generally the Schäfer method is preferable* to that of the Sylvester method.

In using the prone or Schäfer method I wish to remind here of the remark made to me by Professor Schäfer several years ago and which I have quoted above, namely, that "if he were now confronted with the task of resuscitation he would kneel astride over the subject and perform the simple motions of horseback riding without employing his hands and arms at all." This simple manner of employing the prone method could be readily combined with the use of the author's pharyngeal insufflation apparatus, and the operator who is performing the Schäfer method could at the same time manipulate with one hand the respiratory valve and with the other hand regulate, when necessary, the T-tube. *But the operator must learn to move the ring of the valve to the left (expiration) synchronously with throwing his body downward upon the individual and to move his*

*To my mind the apparatus which is here described is practically the most efficient one for the execution of artificial respiration in cases of emergency. It is absolutely reliable; it is very easy to handle and is comparatively inexpensive. My statements which are here made are based upon personal observations. I have, of course, very few opportunities of testing it upon human beings. I hardly need to state that I have no other motive for pleading for the introduction of this apparatus into medical and Samaritan practice than a scientific and a humanitarian interest. The manufacturers are spending immense sums of money for advertising and popularization of their machines. Their agents have no other means of demonstrating the possible usefulness of their respective apparatus than by showing its action upon a rubber bag; I need not discuss here the unreliableness of any of these demonstrations; neither do I need to discuss the inefficiency of the evidence derived from testimonies of some physicians.

thumb to the right (inspiration) simultaneously with the raising of his body from the individual.

We have so far discussed the present methods of resuscitation from the point of view of artificial respiration. But life depends at least as much upon the proper circulation as it depends upon an efficient respiration, and here we must confess that for the present we have no method which would act resuscitatingly upon the circulation, at least no method which could in any way be compared with the methods at our disposal for the performance of artificial respiration. However, it is worth while mentioning the few inefficient procedures at our disposal by which we may assist in restoring the circulation.

1. We ought to keep in mind that in a great many instances the very act of performing proper artificial respiration may render a direct service to the circulation. At a certain low ebb of life the failure of the circulation and that of the respiration form together a vicious circle: when the respiration is inefficient the blood which circulates through the coronary arteries is insufficiently oxygenated, whereby the contractility and conductivity of the heart muscles become greatly reduced and the heart commences to fail. This in turn retards and lowers the circulation within the medulla oblongata, whereby the respiratory (and the vasomotor) centers become asphyxiated. Thus the deleteriousness of the circle continues to increase until both functions finally fail. If before the final failure we could cut through the vicious circle, we may succeed in reversing the process to such a degree as to restore both functions. By employing an efficient method of artificial respiration we may therefore be capable also of helping the failing circulation and thus restore the life of the sinking individual. Thus efficient artificial respiration may be considered as a contributing factor in restoring the failing circulation.

2. Massage is sometimes an invaluable procedure in restoring the heart's action. Massage of the heart is frequently executed by rhythmically striking the thorax at the region of the heart. If employing the Sylvester method for artificial respiration a heart massage can be exercised when returning the arms to the thorax. In some cases massage of the heart was performed from the abdominal cavity through the diaphragm. We shall not dwell here on further details of that method.

3. The injection of adrenalin by the intravenous or intracarotid methods (Crile) may prove as a useful remedy in restoring the heart's action. In experimental work its good effect has been frequently observed.

4. The compression of the abdomen, as we employ it in our method of artificial respiration, drives, as stated before, a part of the blood from the splanchnic region into the heart and from there into the general circulation. In experimental work we have frequently observed that this method is capable of increasing the blood pressure by 20 or 30 mm. of mercury.

The old method of employing various forms of stimulations in resuscitating the apparently dead ought not to be neglected. While it is quite probable that few of these methods, when used alone, have ever restored life, they may nevertheless render some service when used in combination with more efficient methods. The application of heat, friction, the mechanical and chemical stimulations of the mucous membrane of the nose, may sometimes render contributory service. Stimulation of the precordial or pudic regions or of the soles of the feet frequently exert an effect upon the respiration (*i.e.*, if the respiratory mechanism is not entirely paralyzed) and may at the same time affect the vasomotor centers and perhaps also the heart by the way of the accelerator nerves. While all first-aid men must be impressed with the fact that their first attention must be given to the respiration, it is not necessary to impress them that all the other means have no value. Anything which contributes to the resuscitation in the smallest degree should not be omitted, provided that the essential procedures are well taken care of.

Before concluding, I wish to add the following few brief remarks: As it will be seen in my present paper, I omitted the advice given in previous papers, namely, that in the absence of a proper pharyngeal tube to use a mask. After a long experience and a further analysis of the conditions, I came to the conclusion that a mask is liable to do a great deal of harm by driving infectious material, usually present in the nose and the pharynx, directly into the lungs and thus produce a fatal inflammation of that organ. By using the pharyngeal tube that danger is reduced to a minimum. But I wish to emphasize here that even in this method a minimal danger is present, and therefore recommend the employment of this method of artificial respiration *only in emergency cases.* When we find an individual apparently dead we pay little attention to the possibility that our attempts of resuscitation may lead later to some disease of the victim; we would rather see the individual alive, although temporarily sick, than see him dead. Nevertheless, we should reduce this possible danger to its minimum.

In connection with the foregoing remark I wish to make the following brief statement. On account of the difficulties which some anesthetists meet with the introduction of the tube into the trachea, they began to advocate what they term intrapharyngeal or endopharyngeal anesthesia. I wish to go here on record that in my opinion this is definitely a retrograd step. I am not familiar with the details of the methods which some of the advocates of endopharyngeal anesthesia employ. From a general reading of, and occasional listening to, a discussion of that subject, I am under the impression that the methods which they employ are incapable of keeping up the respiration in case this function should fail. It seems to me that anesthetists are not familiar with the facts (or, at least, pay very little attention to it) *that anesthesia reduces greatly the efficieney of the normal respiration.* That patients, nevertheless, survive the anesthetic procedure is due to the fact that the normal function is well provided with *factors of safety,* so that if nothing unusual happens life may continue even with a low degree of respiratory exchange of gases. With my method of pharyngeal insufflation, respiration can be kept up for many hours in an efficient way, but, nevertheless, I advocate its use only in cases of emergency—for the above mentioned reason. From unpublished statements I learned that post-operative pneumonias are not an infrequent occurrence after the use of pharyngeal anesthesia. The contrast between the

intrapharyngeal and intratracheal insufflation ought to be evident at a glance. In the intratracheal insufflation all foreign substances are driven backward. In pharyngeal insufflation, on the contrary, foreign substances are driven directly into the lungs. Furthermore, as a method of anesthesia, I discarded the intra-pharyngeal insufflation very early[12] on account of the profound effect which it produces upon the animal; in several instances I had to continue the insufflation without anesthesia for the purpose of administering artificial respiration for longer than half an hour before the animal started breathing spontaneously.

I wish therefore to be explicit in my statement. I recommend the use of my apparatus for pharyngeal insufflation only for artificial respiration in cases of emergency and I advise especially against its use as a routine method for the administration of anesthesia.

Finally, I wish to call the attention of authorities who are frequently confronted with the need of artificial respiration (superintendents of hospitals, health and police departments, first-aid stations, etc.) that in the method which I described here we possess a reliable and easy to handle procedure and a comparatively very cheap resuscitating apparatus. It is highly desirable that the men who may have to perform the resuscitation by means of this apparatus, should familiarize themselves with the apparatus and the mode of procedure. The apparatus and its use are very simple; but even the most simple thing requires some practice in handling it properly.

TREATMENT OF HAYFEVER AND ASTHMA BY PITUITRIN AND EPINEPHRIN.*

By ERNEST ZUEBLIN, M.D.,

CINCINNATI, OHIO.

ASSOCIATE PROFESSOR OF MEDICINE, UNIVERSITY OF CINCINNATI; MEDICAL DIRECTOR, CINCINNATI TUBERCULOSIS HOSPITAL.

In a former communication (Medical Record, March 3, 1917), I published favorable results obtained by treating asthma cases with pituitrin and adrenalin injections. Since then several cases of hayfever have come under my observation in which a similar treatment was applied with good results.

I need not enter upon a detailed discussion of the etiological factors which are closely related to the current conceptions of immunization and anaphylaxis. Clinical and therapeutic experiences have established the fact that certain individuals present a hypersensitiveness to the pollen of certain blooming plants. These irritating substances gaining access to the respiratory tract are considered the cause of the well-known and distressing clinical symptoms, whilst vaccination with pollen extract seems to attenuate or to prevent the occurrence of the clinical manifestations. The therapeutic results with pollen vaccination are doubtless a great achievement in the relief and removal of the abnormal clinical signs. From the clinical standpoint, cases of hayfever offer much interest, since closer examination reveals certain clinical particularities which deserve our attention, as shown in the following cases:

Case I.—Mr. W. B., age 36, teacher, negatve family history and past history. Hayfever attacks date back for the past 18 years, which manifestations are of extreme violence, attended by burning, tickling sensations in the nostrils, eyes, throat, violent sneezing, serous discharge from the mucosæ of the respiratory tract, with distressing attacks of asthma—particularly in the evening. The exciting causes of such manifestations are the following: Blooming lilac, different gramineæ, roses, dusty, heavy, damp atmosphere. Patient before coming to me had tried all kinds of treatments for nose and throat and various drugs without any success whatsoever.

The results of the physical examination are the following: Patient short built, well nourished, eyes injected, abundant mucous nasal discharge; emphysematous chest, moderate harsh breathing over right apex anteriorly; numerous sibilant râles over both upper lobes anteriorly and posteriorly. Heart, apex in left midclavicular line, fifth interspace; absolute cardiac dullness extending from fifth interspace to upper border of third rib, and slightly outside of the left sternal margin; relative cardiac dullness extends from fifth interspace towards the right and overlaps the right sternal border, reaching as far as the upper border of the second rib. Heart sounds: Over mitral area first sound roughened and distant but no murmur, second sound normal; tricuspid and pulmonary sounds weak, not accentuated; second aortic sound weak. Blood-pressure—auscultatory method—Tycos—112 systolic, 78 diastolic; 34 pulse pressure. Abdomen prominent, nothing particular. Knee-jerks accentuated. Marked dermography of the skin.

Treatment and clinical remarks: Subcutaneous injection of pituitrin, 1 c.c.; Adrenalin chloride solution 1/1000, 0.5 c.c., given on June 6, 1914. Patient reported two days later, felt very well after the injection; came down town in motor car; experienced slight tickling in the nose, dryness, and some watery feeling, but had no sneezing or any further unpleasant manifestations. Since this was my first hayfever case, as a precaution

*Paper presented at the XVIIIth Annual Meeting of the American Therapeutic Society, New York, June 1-2, 1917.

the patient was given one dram t.i.d. of the following prescription: Ammon. iodide, 5j ss; ammon. bromide, 5ii; tincture lobelia, 5j; syrup of tolu, fl. 5ij; peppermint water, q. s. ad. fl. 5iij. Alcohol rub for the skin every morning. June 11. Notwithstanding the hot and close weather and blooming grass, which factors always caused a severe hayfever attack, the patient experienced only a slight tickling sensation in the nose, which lasted for about 5 minutes instead of several hours as in former times. No attacks of sneezing whatsoever. Pulse 81. Blood pressure: Systolic 108, diastolic 70; pulse pressure 38. Patient received another injection of pituitrin and adrenalin in the dose mentioned above. Reported at office 3 days later that he had been feeling fine for two days after the injection. Slight sneezing and burning sensation was noticed during an exceedingly damp, moist and rainy day, but no discharge from nose, and no dyspnea. The injection was repeated without any internal medication, which was discontinued. The fourth and fifth injections were given on June 17 and 22. The weather conditions were the same unfavorable ones as mentioned all the time, but no single attack, no dryness, no sneezing and no discharge whatsoever was recorded by the patient when last seen on July 6, at which time the sixth pituitrin and adrenalin chloride injection was given. The patient was advised to report at the slightest indication of a hayfever attack but no such occurred, whilst all the previous years the severe attacks lasted for three months, with daily paroxysms.

The patient kept well throughout the summer of 1914 and only reported the next year on June 5, 1915, on account of a moderate dry sensation in his nose, with tickling, signs which were always infallible for a hayfever attack. No sneezing spells nor dyspnea were noticed so far. As the only objective signs of interest the heart examination must be recorded, namely, dilatation of the right ventricle—threshold percussion—muffled first mitral sound, relatively small pulse pressure. The extent of the absolute cardiac dullness: apex sixth, interspace, slightly outside of midclavicular line, reaching to lower border of third rib and the middle of the sternum. Relative cardiac dullness extends from the sixth interspace towards the right, overlapping for one inch the right sternal border, reaching upward to the upper border of the third rib. The diameters are for the transverse diameter 5¼ inches, oblique diameter, 5¾ inches; height, 4¼ inches; the surface area of the relative cardiac triangle measuring 11.65 square inches. Heart sounds indistinct, muffled first mitral sound, second sound very distant, accentuation of both second aortic and pulmonic sounds; first tricuspid sound split, roughened, but no murmur. Pulse weak, irregular, becomes faint during bulbous pressure, the rate 78; after pressure is relieved slows down to 66; blood-pressure systolic 106 mm., diastolic 78, pulse pressure 30 mm. Hg. pressure pro one minute 14,560 mm. Few scattered dry râles over the pulmonary hilus posteriorly and in front. Marked dermography, considerable flushing of the skin, conspicuous indicanuria being present.

Treatment and clinical remarks: On June 5, 7, and 9, subcutaneous injections of 1 c.c. pituitrin, and 0.5 c.c. of adrenalin chloride 1/1000 were given, and for 4 days 2 minims of the following solution: Atropine sulphate, gr. 1/40; peppermint water, 5ij. The therapeutic results are summarized as follows: The heart sounds became absolutely normal following the second injection, the heart showing on threshold percussion a lessened transverse diameter, 3⅜ inches—1⅞ inches less; height, 2¼ inches—2 inches less; oblique diameter, 4 inches—1¾ inches less than on the previous examination. The pulse and blood pressure figures and Imin. Hg. pressure were found on

June 7: 90 pulse, 120, systol. 92. diastol. pulse pressure 38. 19,080 mm. Hg. pressure pro. 1 minute.
June 9: pulse 90, 120 systol. 80, diastol, 40, pulse press. 18,-000 mm. Hg. pressure pro 1 minute.
June 11: pulse 80, 118, systol. 70. diastol. 48, pulse press. 15,-040 mm. Hg. pressure pro 1 minute.

Very damp and close weather prevailed. Except a very slight tendency towards sneezing, no typical hayfever attack occurred throughout the entire season and also during the next year, 1916, the patient was reported perfectly well without having experienced any of his former paroxysms.

Case II.—Miss M. K., age 53, school teacher and secretary, reveals a negative family history, mentions in her past history otitis media with remaining deafness following measles; subject to rheumatism during the past 5 years, with stiffening of the fingers and knees. The attacks of hayfever started 20 years ago, returning with great intensity in May every year, lasting for about 8 weeks. The first paroxysms were noticed 20 years ago, whilst spending a pleasant day out in the country in the season of roses. Patient mentions the following symptoms: Sneezing, redness, serous discharge from the eyes, raw feeling of the mucous membrane, cough, cold in the head, rendering nasal breathing impossible, severe attacks of asthma at rest and after exertion, occasionally occurring during the night so that the patient had to get up for relief. These attacks were daily without any change in severity and duration. All previous treatment in former years consisting in nose and throat treatment, in local application of menthol; preparations of pollantin had no result whatsoever. Substances which are thought by the patient as causative factors are roses, timothy grass, dust from the street, from old papers, books, etc., seashore climate. Change of air to the mountains has no influence at all upon the course or intensity of these attacks, which are dreaded very much by the patient at the approach of the pollen season. Digestive functions are slightly impaired, heaviness, belching of gas after meals, acidity, marked constipation. Circulatory disturbances present, dyspnea after moderate exertion, emotional palpitations, perspiration. Tendency towards headaches, dizziness. Sleep good. Frequent eruption of hives, not dependent upon the intake of any food. When getting up patient frequently complains of a thick throat. Patient flushes easily, is subject to chilly sensations without any rise of temperature.

Physical examination of the short-built patient: Conjunctivæ moderately injected, tonsils irregular, not enlarged. Chest—lack of respiratory expansion of left, depressed apex, emphysema over remainder of chest, harsh granular inspiration over left apex anteriorly, the same character of breathing existing over both apices posteriorly with numerous, scattered fine crepitant râles, vocal fremitus normal. Heart—apex impulse fifth interspace, indistinct relative dullness in fifth interspace, 4 inches to the left, 1⅛ inches to the right from the midsternal line; height 3¼ inches, oblique diameter 5½ inches, cardiac superficial dullness, triangular content 8.328 square inches. Heart sounds—mitral first sound very indistinct, weak, resembling embryocardia, second sound also weak, not to the same extent. Over the other auscultatory areas the sounds are very distant and indistinct, no murmur nor accentuation of the second pulmonic sound can be found. Pulse 96, not well sustained, weak, but regular as to rhythm. Systolic blood pressure 108, diastolic 82, pulse pressure 26, which figures were only obtainable by the palpatory, not the auscultatory method; total Hg. pressure pro one minute 18,240 mm.; Hb. 65 per cent. Talquist. Urine—spec. gravity 1,012, no albumin, marked indicanuria. Stomach—testmeal withdrawn 4 hrs. after Leube-Riegel meal 48 per cent. free HCl, total acid 60 per cent. Abdomen and extremities normal. Treatment and clinical remarks—Pituitrin 1 c.c. and adrenalin 0.5 c.c. injections were started at once. The results are recorded below.

On May 15, patient reporting at my office, slight discomfort was noticed at point of injection, moderate headache was present, but no other complaint. As seen from the table, the size of the cardiac dullness had changed considerably, slower pulserate, better pulse pressure, heart-sounds, particularly the first mitral sound, were better

sustained and accentuated. On May 17, no manifestations are reported, patient feeling stronger and well stimulated, the pulmonary findings reveal less moisture. Pulse is full and strong, no more burning sensations are noticed in the nose. Heart sounds are slightly diminished in intensity, patient is advised to take 2 minims t.i.d. after meals of atropine gr. 1/40 in peppermint water 3 ij. May 25, pulse is fuller and stronger, well sustained, patient is feeling excellent notwithstanding the murky weather, a high humidity, and abundant precipitation. Patient reports to have undertaken an automobile ride in the country, with much dust, which exercise in former years always resulted in violent hayfever manifestations, but such a result was not observed this time. Notwithstanding strenuous work at the office, sustained exertions connected with preparations for closing up the house before going West, the patient feels exceedingly well, as quite distinct from former years. The heart sounds are good, embryocardia has disappeared. The same report is given on May 28 and 31, and as seen from the table an attempt was made to decrease the dose of pituitrin, whilst digalen ♏ x, t.i.d. was tried in order that the patient who intended to go West should have a cardiac stimulant whilst exposed to exertion and excitement during her long travel. On June 4, a moderate increase in the size of the heart was found, with a lower pulse pressure, on account of which the dose of pituitrin was raised to 0.8 c.c. The digalen dose was reduced to ♏ viij, t.i.d. and also the atropine to ♏j. The patient was seen on June 7 doing very well and presented at the examination of the heart well sustained heart sounds accentuation of the second pulmonic, higher systolic, a moderate diastolic, high pulse pressure, and a better Hg.mm. pressure pro minute.

The patient on her sight-seeing trip to San Francisco, notwithstanding unaccustomed exertions experienced only slight discomfort while touring in the Rocky Mountains. Some palpitation and cardiac oppression were noticed in climbing, which symptoms cleared away rapidly after rest.

The patient returned home in very good condition and was not heard of until June 5, 1916, when she was preparing to leave the city for her vacation. At that time, a few days preceding her call, irritation of the eyelids and nostrils, moderate watery mucous discharge from the mucous membranes, very moderate sneezing, but no respiratory difficulties were noticed. Again on physical examination the heart showed dilatation, muscular weakness, indistinct heart sounds, particularly both mitral sounds were found indistinct, murmurish, accentuated; split second aortic sound; low systolic, high diastolic and low pulse pressure. The figures of the diameters of the heart are given below, as well those for pulse and blood pressure readings.

	Tr. D.	H.	O. D.	Surf. Sq.In.	P.	S. P.	D. P.	Pp.	Hg. l'P.	Inject. Pit. c.c	Dose Ad. c.c.
June 5	5⅝″	4″	6½″	11 25	78	112	88	24	15,600	0 8	0.
Jun	4¼	3¾	5¾	8.43	75	110	74	36	13,800	1.0	0.2

The patient reported two days later following the first injection, feeling perfectly well, and objectively presented normal heart sounds, regression of the cardiac dilatation, lowered diastolic, increased pulse pressure, a smaller figure for the one minute mercury pressure. The results of the last injection could not be controlled by physical examination but the patient leaving the city for the South, notwithstanding very hot and damp weather, roses and other flowers in full bloom, was entirely free from symptoms suggesting her former "rose-colds." Whilst sojourning in New England during a wet summer, the patient reported that she had experienced only very slight discomfort of occasional watery discharge from her eyes and nose, but never any asthmatic attacks, which were so troublesome in former years. Since the patient was at my office only twice before starting out for her vacation, I had some doubt whether the two injections of pituitrin and adrenalin were sufficient to protect her from any further manifestations of her rose colds. If it could have been arranged to give the patient the pituitrin injections, it is my impression that even the slight manifestations mentioned above could have been averted.

Among my hay fever patients there are four more cases, two women and two men, who were treated by the pituitrin and adrenalin injections. Time, however, and space forbid me to enter into a detailed analysis of their cases. Briefly speaking, on first examination they all revealed dilatation of the heart, with weak sounds, rapid pulse, low systolic and high diastolic blood pressure, low pulse pressure, digestive disorders, particularly marked indicanuria. Under pituitrin and adrenalin injections these cases showed all at least reduction in the size of their heart, better heart sounds, improved blood-pressure findings; symptomatically the attacks did not return, or were lessened in intensity and severity. In giving my personal clinical observations on a few hay fever cases, I am fully aware that definite conclusions from the present observations should not be drawn. From the theoretical and clinical standpoint two points seem of interest, namely:

1. That the symptoms emanating from the respiratory tract are probably not the only ones present; that, at least as shown in the cases referred to above, there may be found definite signs of a cardiovascular deficiency-cardiac dilatation, weak heart sounds, abnormal blood pressure findings, vasomotor weakness, associated with indicanuria of nutritional or intestinal origin, which functional disturbances may be favoring factors for the manifestations resulting from the pollen irritation. Somewhere, somehow, the pollen floating in the air must reach the mucous membrane. Admitted the lack of a vasomotor tonus, a low circulation, and weakened heart condition, the possibilities are that the irritation of the pollen is more apt to cause the distressing clinical symptoms.

2. That from the therapeutic standpoint pituitrin administered in appropriate doses may remove the cardiovascular depression and in some instances cure, or at least alleviate, the clinical symptoms. The making of such a statement does not imply that pituitrin medication is the only substance to be used in hay fever cases, nor does it mean that the pollen vaccination is out of place. As said before, the vaccination treatment has its usefulness and is apt to secure good results. From the clinical standpoint I believe that the attendant signs of vasomotor and cardiac weakness ought to be considered in the outline of treatment for hay fever cases.

Admitting that the posterior part of the pituitary body plays a more important part in human physiology than generally supposed, especially with reference to the vagus nerve, it is at least probable that by the proper therapeutic use of pituitrin we are able to help the patient and secure him better protection from the tedious symptoms attributed to hay fever.

PRICE HILL.

Syndrome Seen in Soldiers with Intestinal Troubles.—Depéchaux describes an augmentation in volume of the abdomen, with ptosis, meteorism and depression of the cupola of the diaphragm as shown by *x*-ray examination. These phenomena appear only in predisposed subjects and are of hysterical nature. They appear through autosuggestion consecutive to colitis or dysentery.—*Le Progrès Médicale.*

RECENT LITERATURE PERTAINING TO VITAMINES; THEIR APPLICATION IN INFANT FEEDING.*

By LOUIS FISCHER, M.D.,

NEW YORK.

THE term vitamine is used to designate the group of substances in the animal diet which are present in minute traces, whose nature and chemical constitution are unknown, and whose absence will result in a series of pathological changes which can only be overcome by addition of these essential factors. The name is simply a class designation, and is used as such (A. B. Macallum).

Since the publication of Funk's book on the vitamines in 1912, research has been stimulated, so that a large number of scientists, amongst whom Bradden, Cooper,[1] Mendel, Seidell,[2] Goldberger, Williams, and Vedder[3] should be mentioned—nearly all have confirmed the results of Funk.

During the last five years our knowledge of the metabolism of fats, proteins, and carbohydrates has been considerably enriched, and we have learnt why we have had so many feeding failures. Our knowledge of the internal secretions has enlightened us in many ways, likewise the discovery of the amino-acids and the lipoids; their rôle in the digestive process are all new and valuable factors in infant feeding, but, they have failed to solve the problem.

We have learned that just as we find some foods high or low in fat and proteins, so we find some foods high and others low in vitamine; therefore, in giving a mixed diet we give a normal amount of vitamine, although in the preparation of various foods the vitamine is frequently abstracted or destroyed.

Many cases of malnutrition are met with where large quantities of food have been consumed but poorly assimiliated. The faulty metabolism of the fat, or protein, or carbohydrate shows that something was lacking. We have learned that unless the food ingested contains sufficient vitamine there will result partial starvation.

It is a well known fact that the too exclusive use of ordinary white flour and of most carbohydrate foods such as sugar, hominy, tapioca, sago, and the starches, and certain kinds of cornmeal will produe polyneuritis in fowls, and beriberi in man. The deficiency diseases, especially scurvy, are frequently found in institutions where the above diets have been rigidly enforced and the antiscorbutic factors such as the fresh meats, fresh fruit juices, fresh milk, and especially fresh vegetables, withdrawn.

Funk experimented with autolyzed yeast and found that when 3 per cent. of yeast is added to food given to white rats, growth was stimulated.

According to McCollum, Simmonds, and Pitz,[4] when young rats are fed a mixture of 60 parts of wheat embryo and 40 of dextrin, a mixture which furnishes about 20 per cent. of protein, very slow growth takes place, and the animals may live for 4 months or more without loss of weight. The addition of calcium lactate (2 per cent.) to this food mixture will, at any period of their growth suspension, induce a noticeable increase in body weight.

Although yeast has been extensively used for feeding cattle for a number of years, its use for human consumption has been suggested only recently, during the war, owing to the scarcity of meat. As a meat substitute it was strongly recommended by Schottelius[5] who has used it in quantities of 50 to 75 gm. daily, in addition to the ordinary diet, and claims that it is well utilized in the human body.

Funk's results show that young rats can live on yeast as the sole nitrogen source for quite a long while, although it has not yet been proven whether they can subsist on it indefinitely.

According to Funk[6] a definite relationship exists between the onset of certain deficiency diseases and the amount of carbohydrates consumed. This has since been corroborated by Braddon and Cooper.[7] It has been known for some time to those who have studied beriberi from the clinical standpoint that, with an increase in the consumption of polished rice, the onset of the disease can be hastened. This was attributed to the presence of toxic substances in the rice. It was also known that the deficiency diseases occur when proprietary foods consisting chiefly of starch, make up the bulk of the dietary. By actual experiments on animals, Funk[8] was able to ascertain that "by decreasing or increasing the quantity of polished rice or even of pure starch, beriberi can be produced slowly or quickly as desired. It has also been found that in beriberi the blood sugar is increased, especially in those cases in which large percentages of starch are given in the diet. Occasionally in the literature clinical data may be found referring to the increase of blood sugar in certain deficiency diseases as in scurvy, but the matter has not been studied systematically, and no data can be found relating to blood sugar in acute beriberi or pellagra occurring in man. It appears that there is a very definite relationship between the vitamine present in the food and the amount of carbohydrates which have to undergo metabolism. Accordingly the fact must be emphasized that a certain amount of vitamine can take care only of a limited amount of carbohydrate."

Another interesting point brought out by Funk[9] is that animals fed on white rice showed very marked changes in the chemical composition of the brain. Remembering that the most characteristic feature of deficiency diseases is a group of symptoms arising from the central nervous system his findings should be regarded as very important.

The clinical aspect of vitamine therapy has been studied by M. Stark and Edelman[10] at the Post Graduate Hospital and their interesting report deserves careful consideration.

The exclusive feeding of carbohydrates such as hominy, tapioca, sago, and the starches is to be condemned, for if continued it will produce intestinal disorders.

Variety of Food.—To give the live factor or vitamine necessary to the proper assimilation of food we must give a mixed diet of fresh vegetables, such as potatoes, spinach, dandelion, carrots, beans, and peas, in addition to fruit juices, such as orange, lime, and pineapple juice, fresh milk, fresh meat, and hard boiled yolk of egg, the outer coats of

*Read before the Section on Diseases of Children, American Medical Association, June 6, 1917.

wheat, oats, and especially barley are very rich in vitamine. Natural or so-called black cod-liver oil has been extensively used, likewise butter-fat, to promote growth and stimulate metabolism because of their vitamine content. The substitution of lard has been a failure. The excellent results obtained by Kassowitz in his well-known phosphor-cod-liver oil therapy in rachitis is due, in the light of our present knowledge, to the vitamine content of the cod-liver oil.

One must not wait for definite scorbutic symptoms nor for rachitic symptoms during infantile development, but vitamine in some form should be added when the infant is several months old.

There are three symptoms which deserve emphasis as showing imperfect metabolism of food elements. They are: (1) Restlessness, irritability, loss of sleep, head sweating; (2) greenish liquid stools containing curds or mucus; (3) loss of, or stationary weight.

When vitamines are taken into the body their action is to stimulate the internal secretions. By setting free these secretions they act as hormones. These hormones again stimulate the enzymes.

To guard against deficiency diseases vitaminic foods should be given as early as the first few months of life. Infants will digest spinach and other vegetable juices, without gastric disturbance, during the early months of infancy. They appear markedly improved by this addition to the diet.

The following cases are given as examples of malnutrition and faulty metabolism in which the nutrition was improved and the infant more satisfied when the vitamine-containing food and vegetable juices were added to the dietary. The character of the stool was changed within a few days from a greenish mucous stool to one of a yellowish pasty consistency. It may be interesting to note that no medication was given.

Case I.—E. J. S., female infant, was born of healthy parents on November 3, 1916. Weight at birth, 6 pounds 2 ounces. Was breast fed from the fourth to the twelfth week, but gained only one pound. When seen by me there was a seborrhea covering most of the body, excoriated buttocks, and six to ten greenish mucus stools containing curds were passed in twenty-four hours. The infant was restless, dissatisfied, cried most of the day and night, and seemed hungry. It nursed one-half hour or longer every two to three hours. Breast feedings were alternated with a 2 per cent. modified cow's milk. Lactose, sucrose, and maltose were tried in turn, but all disagreed. After several weeks of the alternate feeding the mother's milk was discontinued, and a wet nurse's milk substituted. This also proved unsatisfactory and the infant was put on a modified cows' milk and vegetable juice diet. When ten weeks old a 2 per cent. fat mixture was given. One-half ounce of orange juice was given every morning, and a half-ounce spinach juice, made from freshly boiled spinach leaves, was given every evening. Grated zwieback (half a piece) was given with each feeding. A steady gain commenced, and this diet was assimilated. The weight at the age of thirty weeks was 16 pounds 6 ounces. The infant now at seven months of age receives cereals in addition to vegetable purées, orange juice, and one quart of milk daily.

Case II.—E. L., child of a druggist living at Jamaica, L. I., was first seen when five months old. The mother said the infant had eight to ten liquid stools containing mucus daily for the last month. The feeding consisted of forty ounces of a modified whole milk formula. The infant weighed seven pounds at birth. When seen by me at five months of age the weight was 10 pounds 9 ounces. Eleven greenish liquid stools containing stringy and jelly-like mucus were passed during the previous twenty-four hors. The whole milk formula was changed to one of skimmed milk. A half ounce of orange juice was given once daily, also a heaping teaspoonful of freshly boiled chopped spinach was given daily. Within a few days the character of the stool had changed to a more solid consistency. Crushed zwieback was added to two feedings daily. The infant began to gain at an average of five to six ounces weekly and now weighs over fourteen pounds.

The above two cases are submitted as further evidence of what has already been published in the interesting report of Stark and Edelman at the Post Graduate Hospital. When it was possible to obtain autolyzed yeast, the same was given in doses of from 10 to 60 drops each feeding. The vitamine content of the autolyzed yeast certainly stimulated the digestion and assimilation of the food to a noticeable degree, and I am convinced that it merits further use and consideration.

INFECTIOUS ARTHRITIS.*

By J. W. TORBETT, B.S., M.D.

MARLIN, TEXAS.

The word rheumatism is a general term which has been used to signify pain in a joint or muscle, regardless of its cause. The more practical or scientific method, of course, in all cases, is to determine, if possible, the etiological factor in every case and modify the term arthritis with an adjective indicating the specific causative agent. This, however, is not always possible to do, and hence the word toxic or infectious is used to indicate that some bacteria, bacterial or other toxin, is the cause.

Etiology.—Goldthwait, Painter, and Osgood divide arthritis into atrophic, hypertrophic, infectious, luetic, and tuberculous, and think the streptococcus, staphylococcus, pneumococcus, gonococcus and tubercle bacillus are the usual bacterial agents producing arthritis, but that the bacteria themselves often cannot be isolated from the joints, their toxins being sufficient to produce the effects. Most authorities now consider them all as infectious or toxic.

The diplococcus of Poynton and Paine has been accepted by many as the etiological agent in those acute forms of migratory arthritis with acid sweats, etc., now called rheumatic fever.

Edward C. Rosenow, by his recent experiments, has shown that the streptococci are very human in their temperament and characteristics, being changed in virulency and other properties by their

*Read at a meeting of the McLennan County Medical Association.

food and environment. Some strains are virulent and some non-virulent; some select gall bladder, some the heart tissue, some the skin, as in erysipelas or erythema nodosum, and some prefer the joints as their food and habitat. He even thinks that peptic and duodenal ulcers are caused by them. In the Mt. Sinai Hospital the *streptococcus viridans* has been isolated from the endocardium and joints of many cases of arthritis which produced similar symptoms injected into rabbits. The invetigations of Victor C. Vaughan into the parenteral digestion of foreign protein compounds, which includes bacteria as well as amino acids in the circulation, digested by the cell enzymes, have shown that fever and other serious symptoms often result therefrom, anaphylaxis being probably one such result.

The various bacteria or their toxins mentioned above and the *Spirocheta pallida* are the causative agents of most cases of arthritis, though the foreign protein compounds absorbed from the alimentary tract may act as exciting factors in many cases.

The universal enemy of mankind, constipation, now recently called intestinal stasis, which is simply imperfect alimentary drainage, causes increased bacterial proliferation. The antitoxic and bacteria-destroying functions of the liver are impaired by this overwork caused by the high protein dietary and increased bacteria, and later the thyroid, pituitary, adrenals, pancreas, and kidneys, one or all, may likewise suffer. This impairs nutrition and lowers the powers of defense, thus making the system more susceptible to the bacteria and their toxins.

Dr. Goldthwait wrote an article recently dividing people into two classes: the wolf or carnivorous type, and the ox or vegetarian type, according to their distinctive anatomical peculiarities and natural habits. The ox type, with broad joints, high cheeks, is naturally vegetarian, and if forced to live upon a high protein diet will be more readily disposed to arteriosclerosis, gout, nephritis, etc. The ox type is more susceptible to the toxic effects of certain amino acids of protein foods. The wolf type is more lithe, smooth, and has a shorter alimentary canal, and can thus metabolize proteins better, without serious consequences.

In an article printed in the March, 1902, issue of the *American Journal of Dermatology and Genito-Urinary Diseases*, the writer first reported ten cases of chronic arthritis caused by urethral stricture, or contracted meatus, all relieved by dilatation and drainage. I stated therein that most rheumatic and neuralgic conditions, I thought, were due to a violation of that well-known surgical principle—drainage. I still believe that statement is true. There is present in some mucous membrane of the body, between the nose or mouth and rectum, the kidneys and meatus, the tubes and vagina, a focus of infection characterized by (1) abnormal retention, (2) fermentation or bacterial proliferation, (3) irritation, (4) absorption. Back of every such stricture or contracted meatus in those cases I found a tender, irritated spot.

These four things are always present, it matters not what bacteria may be the causative agents. The focus of infection should be located, if possible, and drainage established. It may be imperfect drainage from an abscess at the roots of the teeth, pyorrhea, frontal sinus, antrum, tonsils (often imbedded with no soreness), the gall bladder, colon, appendix, tubes, uterus, prostrate, urethra, or rectum from a fistula or tight sphincter. I could recite many cases from our own experience to prove the above sources of infection. One patient this past summer, with an affection resembling a one-sided Jacksonian epilepsy, was relieved by a tonsillectomy, and many cases of arthritis may have been thus relieved.

I am coming more and more to recognize the great importance of a complete history of each case as to origin, onset, and first symptoms. The sore throat will always precede and often subside a few days before the arthritis begins, when the tonsils are the source of the infection.

Differential Diagnosis and Treatment.—The acute gonococcic arthritis usually begins with fever and migratory pains for 24 to 36 hours, then one or more joints become sore and diffusely swollen and remain so, other pains ceasing. A careful history will show an acute gonorrhea of 12 to 18 days' duration, in which the discharge stopped two or three days before the arthritis began. The immediate application locally to the inflamed mucous membrane, if possible, for 5 to 8 minutes two or three times daily, of a 2 per cent solution of magnesium sulphate, with 1 per cent of carbolic acid, will often reverse the osmotic action, drain the mucous membrane, start up the discharge again, and stop the arthritis which otherwise would continue for weeks.

There is also one other condition which is so often called rheumatism and treated as such with very disastrous results to the patient. It is acute osteomyelitis. The careful history will enable one to diagnose it readily. Quick onset by chill and fever, sharp boring pain in the bone near but *not in* the joint made worse by tapping, with no swelling nor visible redness the first few hours. John B. Murphy claimed that this is strictly a surgical condition and should be so treated within 24 to 36 hours. If no surgeon is present, he says, take a gimlet, boil it and bore into the region of the pain in the medullary cavity, when after a few minutes pus will exude and relief follow. If not thus treated the patient will be sick for weeks and perhaps rendered a cripple for life.

Trauma is an exciting etiological factor in these cases. With a large aspirating needle I have removed two or three drops of fluid and relieved a streptococcic periostitis. Free opening, however, is the treatment. A chronic luetic or tuberculous arthritis or osteoarthritis may closely resemble each other, requiring the luetin or Wassermann test to determine which is present. One or both of these tests should always be made in all chronic cases having pain and soreness especially when worse at night.

A Roentgenogram will often clear up the diagnosis and I have several plates showing this point. The staphylococcus infection has moderate fever and will terminate by formation of pus, as a rule.

The pneumococcus arthritis has sore muscles, diffusely swollen joints, moderate fever, and may change suddenly from all the joints to the lungs, giving an acute lobar pneumonia. The streptococ-

cus infection has more fever, red tongue, often chilly sensations, cool, moist skin, rapid pulse, and frequent heart involvement, and is hardest to cure. The *Diplococcus rheumaticus* arthritis, which I think is often aided by the colon bacillus, has red, hot swollen joints, changing from one to another joint, quickly bounding pulse, coated tongue and acid sweats. Ammonium chloride and sodium salicylate preceded by a mercurial purge, will relieve this type in a few days, as a rule. If the stomach will not bear large doses of aspirin or other salicylates, as it often will not in such cases, the salicylate and bicarbonate of soda may be given in hot water as a clyster. Or the chemically pure sodium salicylate, in 10 to 30 grain doses, may be given in 50 c.c. of sterile water intravenously as recommended by Conner.

A word of caution against giving medicines intravenously. They must be neutral or slightly alkaline. Most medicines are bacteria-free when opened unless touched by hands, and may be decomposed by boiling. I have had some very excellent results by giving the sodium salicylate intravenously, but the urine should be examined always every day to detect possible renal irritation. Doses of 200 to 300 c.c. of a 2 per cent. solution of magnesium sulphate have been given intravenously by Harrower and others for true streptococcemia with good results in puerperal cases and in erysipelas, and should be tried in streptococcal arthritis. The treatment, however, in all cases should be under four heads corresponding to the four etiological steps and to the bacteria present: (1) Drainage or removal of the focus of infection, by whatever means necessary according to its location. (2) The sterilization and healing of that focus by antiseptics, salicylates, mercurials, castor oil, or thymol and charcoal in the alimentary types, as recommended by Geronne in the case of typhoid carriers. (3) The elimination of bacteria and toxins already in the system by means of baths, purgatives, diuretics, and massage. (4) The building up of the powers of resistance to prevent or antagonize absorption and assist elimination by means of sunshine, fresh air, deep breathing, a good balanced ration with iron, arsenic, and tonics. Vaccines are useful in the chronic recurrent cases, autogenous are preferable, but the mixed polyvalent vaccines often help. All vaccines are irrational in acute conditions, with high fever, unless given at the very onset. The thyroid and thymus glands have helped much in many chronic cases, especially in patients with dry skin, thin dry hair, slow pulse, no fever.

Statistics are usually very tiresome and very one-sided, depending upon the physician's viewpoint and experience. The surgeon comes to think that the tubes, gall-bladder, and appendix are the sources of most infections. Many laryngologists have regarded the tonsils as the source of 40 per cent of all cases of rheumatism. The internist believes a one-sided or excessive dietary with constipation, intestinal stasis, or autotoxemia to be the most common trouble. The dentist accuses the teeth and alveoli as such. The genito-urinary man reports 65 per cent. due to infected vesiculæ seminales. Each partisan quotes with enthusiasm some high sounding, far-away name as his authority, then often fails to use his own eyes and gray matter as he should. All authorities are human beings, in a measure one-sided and subject to err.

Fifteen years ago I saw a bad case of rheumatism recover and gain 30 lb. after having the teeth extracted, giving drainage in pyorrhea, but I have seen many cases of pyorrhea that had no rheumatism at all. We now know, according to Hartzell and Rhien and others, that it is not pyorrhea but the *Streptococcus viridans*, from the dental granuloma of the crowned or filled tooth in which the root canals were not perfectly cleansed, sterilized, and closed, that the infection comes to form alveolar abscesses and systemic infection. Pain is often not present and a Roentgenogram is the only means of showing this condition.

I shall give you briefly a résumé of cases from all walks of life classified according to etiology so far as we could determine. Many cases are classed under two or three heads. To May 1, 1916, according to our statistics for the past four months, we treated in all 611 cases, 10 per cent. of that number being neuritis and 31 per cent. so-called rheumatism. Of these 251 cases of rheumatism and neuritis 40 per cent. lived on a high protein diet, had constipation and indican, oxalate of calcium or urobilinogen in the urine, indicating the alimentary canal as the probable source of the trouble, 21 per cent. had chronic inflammation of the nose, throat or tonsils, 16 per cent. began with fever or so-called grip, being an acute respiratory infection. 16 per cent. showed no discernible cause unless hereditary, 10 per cent had bad teeth, which does not include those that might have been shown up by the Roentgenogram as due to alveolar infection. 7 per cent. were due to gonorrhea, 3 per cent. to lues, and 1 per cent. to deficient thyroid glands.

SYPHILIS AND PREGNANCY.

By BURTON PETER THOM, M.D.,

NEW YORK.

THE influence of syphilis upon pregnancy has attracted the attention of syphilologists and obstetricians from the days of Paracelsus to the present. The knowledge gained in the past ten years has added zest to its perennial interest and has wrought great changes in our views so that the aphorisms of the teachers of a former time have been relegated to the limbo of ideas no longer held as true.

Eighty years ago Colles formulated the law which bears his name: "A child born of a mother who is without any obvious symptoms, and which, without being exposed to any infection subsequent to its birth, shows the disease when a few weeks old, this infant will infect the most healthy nurse, whether she suckle it, or merely handle and dress it, and yet this child is never known to infect its own mother, even though she suckle it while it has venereal ulcers of the lip and tongue." In 1865 Profeta made the statement which has since been known as Profeta's Law: "A healthy child born of a syphilitic mother could be suckled by her or a syphilitic wet-nurse with impunity."

For many years these oracular expressions went unchallenged. Coupled with the fact that florid syphilis in the pregnant woman was a frequent cause of abortion and still-birth they represented

practically about all we knew concerning the disease in its relation to childbearing. Since the discovery of the *Spirocheta pallida* and the introduction of the Wassermann test we know the *raison d'être* of these laws and accordingly have grave doubts as to their verity. Since 1905 the literature on the subject has been voluminous, not to say confusing. But now, out of this mass of conflicting opinions, certain facts have been established which enable us to reach conclusions resting upon a scientific basis. It is my purpose in this communication to present these facts.

The Wassermann test has allowed us to arrive at a much clearer insight as to the incidence of syphilis than heretofore. We have learned that it is present, especially in a masked form, much more frequently than was supposed. We have also been made aware that absolute dependence cannot be placed on a serological reaction in diagnosing syphilis either in the pregnant woman or her child. I have not space to go into detail why this is so; indeed, authorities are still divided as to the reasons. Only, I might add in passing, that all women, whether pregnant or not, are more or less aberrant to the Wassermann reaction. We can affirm too, which was formerly denied, that paternal infection can and does occur, although rather infrequently.

The peculiarity which the pregnant woman affects toward the Wassermann is shown in other ways that are still more puzzling. In pregnant or parturient women the milk may react positively and yet syphilis may not be present; the reaction however is not marked—one or two plus. Scarlet fever occurring during pregnancy will give rise to a positive reaction, also in carcinoma and puerperal sepsis. Patients with eclampsia always give a strongly positive reaction. The condition known as latent maternal syphilis—where syphilitic spermatozoids exist in the woman's genital tract—not only creates an immunity to the disease but also against a positive Wassermann because these women not only have antigens in their breast milk but in their blood serum as well. These women may remain in good health indefinitely and yet convey syphilis to their offspring through the ovum, decidua or placenta.

Numerous observers have found that not much reliance can be placed in blood for a Wassermann taken from the umbilical cord. While it is undoubtedly wise to do so as a matter of routine, yet the most absolute test is to search for the *Spirochæta pallida* in the cord itself. The organism should be looked for in the walls of the vein and the connective tissue stroma. In a suspected case a section of the cord should be preserved in a formalin or Ringer's solution and later examined by a bacteriologist. Examination of the placenta is not so reliable, as it not infrequently happens that the spirochetæ cannot be found in the placental tissues, although the woman is patently syphilitic. Usually, however, they can be found and when present indicate not so much the presence of syphilis in the mother as its existence in an active form in the child. As strongly presumptive evidence of this is the fact that the organisms when found are always on the fetal side of the placenta. This is especially interesting because latent syphilis in the mother is undoubtedly derived from an infected fetus. The organisms may lie dormant for an indefinite period and after the woman has borne several healthy children she may develop the disease. It can thus be assumed with almost complete certainty that infection of the mother occurs through the fetus by way of the umbilical vein or the ruptured vessels of the chorionic villi. The antigens thus formed allow the mother to nurse her syphilitic child. If these antigens cannot be found in her milk she cannot nurse her child without grave danger of becoming infected herself. Should the mother be syphilitic and the child proven to be healthy, then the child should be fed artificially.

The latter part of this last paragraph naturally brings us to the discussion of Colles' and Profeta's laws. From what has been already stated the reader can readily infer that these laws are no longer accepted. The explanation of the apparently healthy mother nursing her syphilitic child, is to be found in the latent syphilis and the antigens in her milk. The same is true of the apparently healthy child suckling from the syphilitic mother. It is a latent syphilitic. We know now that it is the fetus which conveys the disease and that no woman can give birth to a syphilitic child without herself also being syphilitic; although the disease may be, and often is, dormant for a long period of time.

A clinical diagnosis of syphilis can be made from the placenta within certain limits. Evidences of the disease are found in the placenta in 70 per cent. of all cases. This, in spite of the fact that the child may show no signs of lues. It is apparent in some cases that the disease has exhausted itself on the placenta and in consequence the fetus is but slightly affected. It is also well known that infants who have syphilis do not always show symptoms at birth nor for a considerable time thereafter in a large percentage of cases. The child may exhibit symptoms of syphilis and yet the placenta may be perfectly normal in appearance. This is the exception, however, rather than the rule; the placenta shows certain signs which if not pathognomonic of the disease are strongly suggestive of it. Almost invariably there is a marked disproportion between the size of the placenta and the size of the child. In syphilis the placenta is decidedly larger. Between a normal child and a normal placenta the proportion by weight is about 1 to 6. In syphilis this is reduced 1 to 4 or even 1 to 3. Pinard has pointed out that the amount of amniotic fluid is also increased. I desire to say in passing that the disproportion between the placenta and child is, in my opinion, more apparent than real because the syphilitic child is often under weight.

The syphilitic placenta shows deep sulci between the lobes which causes the cotyledons to appear more prominent. Its color is paler and its surface is covered with yellowish white patches. Its substance is extremely friable and on section has a mottled appearance that has been likened to sausage meat. The vessels of the cord are visibly thickened, although this is sometimes present without syphilis. When the fetus is born dead the cord is often edematous and the vessels may be plainly seen, shining through the swollen cord. Wharton's jelly may be absent. The amniotic fluid may be increased to such an extent as to constitute hydramnios. This is to be accounted for by the placental

lesions incident to the disease. It may be due to a syphilitic cirrhosis of the liver. The changes occurring in the placenta are in most instances the cause of fetal death.

The condition known as habitual death of the fetus is frequently due to syphilis. The child dies in each succeeding pregnancy, usually between the thirtieth and thirty-fourth week, and is soon thereafter expelled. It cannot be denied that syphilis tends to the formation of monsters and of children malformed to a lesser degree. It is not true, however, that recent syphilis transmits itself as congenital syphilis and tertiary syphilis causes malformations. While syphilis is undoubtedly the most frequent cause of abortion—Charpentier found that in 781 luetic pregnancies there were 302 abortions, and Miller states that 70 per cent. of luetic women abort—the consensus of opinion among modern observers is that syphilis does not cause abortion as frequently as was formerly supposed; nor does it follow that every macerated fetus is syphilitic.

In the study of syphilis and pregnancy from the standpoint of the clinician the observations of Mangiagalli are worthy of note. He recognizes four conditions: viz., both parents syphilitic when conception occurs; the mother alone infected; the father alone infected; the mother becomes infected after conception, both parents having been healthy prior to conception. His conclusions are that an apparently healthy child born of a syphilitic mother is syphilitic although the syphilis is latent. When the mother becomes infected after the seventh month the disease in the child is apt to be less severe than if the infection occurred earlier in pregnancy. He could discover no direct relation between a positive Wassermann and the clinical manifestations of syphilis. When both parents are syphilitic the child inherits the disease in about 75 per cent. of births. When the mother alone is syphilitic the child inherits in about 60 per cent. If the father alone is syphilitic the child inherits in from 10 per cent. to 20 per cent.

Syphilis is always to be regarded as a grave complication of pregnancy. It increases puerperal morbidity more than any other cause. Many cases of nephritis occurring during pregnancy can be traced to syphilis. Sepsis is more apt to occur in syphilitic women than in those who are healthy. Cicatricial stenoses of the os due to syphilitic lesions may cause undue delay and complication of labor. The same is true of edema of the cervix due to active syphilis.

Syphilis in the pregnant woman should be treated the same as when it occurs otherwise. That is, salvarsan, mercury and potassium iodid should be exhibited sufficiently and properly to cure the disease. In the treatment of pregnant women, however, there are certain refinements which should be observed in order to attain the best results for the mother and her unborn child.

In giving salvarsan it must be remembered that the drug has been known to cause premature expulsion of the fetus; but in my opinion this danger is remote. If the woman's veins are sufficiently prominent the salvarsan should be administered intravenously, unless she is suffering with myocarditis or if her blood pressure is abnormally high. If her veins are not prominent enough and for the other causes mentioned the salvarsan may be given by the rectum. A saline is given and after the bowels have moved the lower bowel is thoroughly cleaned with a normal saline enema; after which the salvarsan solution is allowed to flow into the rectum through a catheter attached to a glass funnel. This method while not much used is almost as efficacious as when the drug is injected intravenously. It has the advantage of not increasing the blood pressure, does not produce "water sickness" and is much easier to give to a nervous patient. Should the woman be threatened with eclampsia salvarsan and mercury should be withheld until the urine is free from albumin.

I do not advise intramuscular injections of insoluble mercurials, such as the salicylate or grey oil, in pregnant women—or in any woman for that matter. My reason for this is that when such a menstruum is injected into the buttocks the layer of fat prevents its absorption and painful abscesses are prone to occur. If the patient's veins will permit I prefer to inject the mercury intravenously. A solution of bichloride or mercury benzoate is prepared so that each ten minims represents 0.006 of the drug. The initial dose is ten minims in 15 c.c. of warm normal salt solution. The procedure is the same as when salvarsan is given, only that the blood is allowed to run into the syringe and mix with the solution before it is injected. By so doing the chemical combination which thus occurs renders the solution non-irritating and the danger of phlebitis is avoided. When properly done absolutely no ill effects are produced (which cannot be said when horse serum is used) and it is the most efficient and promptly acting method of introducing the medicament into the system. The patient should receive two injections a week for six weeks. Treatment should then cease for a month and then be renewed. If it is not possible to give mercury this way the next best way is by inunction. During the course of her pregnancy the woman should receive from sixty to ninety inunctions; each thirty inunctions from four to six weeks apart. In giving inunctions it is best to give one each day for six successive days and then rest the patient a day, on which a hot bath is taken. I am in the habit of giving potassium iodid during the course of mercury and for a week or two thereafter, as it assists in eliminating the mercury and as mercury acts best in a state of flux, *i. e.* while being eliminated, the maximum effect is thus obtained. Patients under mercurial treatment should rinse the mouth several times a day as a guard against stomatitis. As pregnant women sometimes have trouble with their teeth the services of the dentist should be requisitioned if necessary. Rest and a tranquil state of mind should be encouraged. The last the medical attendant can materially aid in by maintaining an optimistic outlook. The bowels should be cared for by the administration of a mild aperient as occasion requires. Sexual intercourse should be forbidden after the third month. In those cases where it is not possible to give inunctions, the mercury may be administered by means of suppositories after the manner of Lanney.

These patients require no other treatment, the mercury and salvarsan being sufficient to overcome any anemia that may be present. In some instances

a bitter tonic may be given to improve the appetite. Treatment should be persistent; careless, casual treatment is, in my opinion, almost as bad as none at all.

1632 Avenue A.

COMPLETE THROMBOSIS OF THE ABDOMINAL AORTA;

WITH THE REPORT OF A CASE.*

By ROBERT A. KEILTY, M.D.,
FIRST LIEUTENANT, M. R. C., U. S. ARMY.

Thrombosis of the abdominal aorta is relatively uncommon, though not rare. It may be divided into partial and complete. Partial mural thrombi, with and without organization, are frequently met with over plaques of advanced arteriosclerosis. Complete obstruction, however, above the bifurcation of the iliacs, aside from aneurysm, is not so common. The present case falls under this latter group.

The literature for the past several years averages about three or four cases a year. One case, that of Moschowitz, is interesting. This began as an infection at the umbilicus, a thromboangeitis in a baby shortly after delivery, and terminated in complete thrombosis of the abdominal aorta.

I am in debt to Dr. Alfred Stengel and the staff of the University Hospital for permission to use the following history:

A. G., a white male, was admitted May 12, 1913, complaining of weakness. He stated he had been well until a year ago, when he had asthma for nine weeks. Following this, and continuing to admission, he was short of breath. This was not constant and was more marked after exertion. It was now sufficient to keep him from work and accompanied by epigastric pain referred to the heart and through to the back. He stated he had done light work most of his life, except for a short time in an iron-rope factory. He has had no serious illnesses, denied venereal diseases and used alcohol daily, but moderately, except for a time when he was a watchman in a brewery. His physical examination revealed a pallid complexion, with a dilated and weak heart. The blood pressure was systolic 215, diastolic 160. Urine analysis: dark, flocculent sediment, specific gravity 1030, acid, light cloud of albumin, great many hyaline, dark and light, granular casts, some mucus and epithelium. After treatment his blood pressure became systolic 165, diastolic 130.

June 9, blood: R. B. C. 5,450,000, W. B. C. 15,200, hemoglobin 85 per cent, polymorphonuclears 75 per cent, lymphocytes 21 per cent, large mononuclears 2 per cent. June 10. Phenolsulphonephthalein test showed zero for the first hour, 13 per cent for the second. June 11. Blood pressure, systolic 155, diastolic 115. June 14. The patient complained of severe pain in both legs and this was increased upon movement. A large purpuric patch appeared on both legs, which increased in size and depth of color. This has resulted on this date in a large bleb, and it was first noted that a blue spot appeared on the right toe. Some bloody material was coughed.

June 15. Examination revealed diffuse purpura over both thighs and knees. The legs were cold, especially the feet. No pulse could be obtained. He had some power in the thigh muscles, but could not move the feet or toes. Both femoral veins were full and red. June 16. The toes were bluer and more shrivelled. June 17. The legs above the knees were warm, and the feet seemed less intensely cold than before. They were bluer and more shrivelled, and the lower legs a deeper hue. Abdomen was swollen, but tympanitic throughout. Cardiac sounds were of poor tone and sweating was profuse.

*From the McManes Laboratory of Pathology of the University of Pennsylvania. Presented to the Philadelphia Pathological Society.

June 22. Patient continued to do poorly. Sweating was profuse. Twitchings were present over the entire body. The tympanitic abdomen was very persistent and resistant to treatment. The bowels became incontinent. A large bleb and superficial ulceration appeared on the lower back. Typical Cheyne-Stokes respiration followed and the patient died.

On admission the temperature was 97.1°, respiration 20, pulse 95. The temperature rose to normal, fluctuating between 96.3 and 99.3. Respirations increased gradually to 35 and the pulse as high as 110. On June 19 the temperature had risen to 104, the pulse to 120, and respiration to 32, and remained so until death.

The following is a brief autopsy protocol: A. G., 4220-13-86. June 22, 1913. Permission was granted for an abdominal incision only, without complete autopsy. The body was that of an adult white male about forty years of age. The lower extremities were swollen, dark blue and covered with large liquid blebs. This extended to the inguinal region. The abdomen was markedly distended and upon incision contained some bloody fluid. The intestines were black and friable, so that they were easily torn upon manipulation. The abdominal organs showed a picture of advanced putrefactive changes, although the body was dead only a few hours. The kidneys were swollen, had multiple infarcts, and microscopically showed a diffuse necrosis with an underlying glomerulonephritis. The spleen was the seat of multiple older infarcts, soft and mushy.

The heart was enlarged, the musculature pallid, with a densely adherent clot in the apex of the left ventricle. This was considered grossly an acute mural endocarditis, but the microscopical sections did not bear this out. The valve leaflets were free from acute inflammation. The aorta showed a moderate degree of intimal arteriosclerosis, without large plaque formation. The abdominal portion was completely closed by a fresh currant jelly and marantic clot, which grew older as one went down and which was quite fibrinous at the bifurcation of the iliacs. This thrombus extended down the femorals as far as it was possible to dissect.

This case presents a man suffering with a cardiorenal lesion for at least the period of a year. This progressively became intensified and terminally resulted in a thromboangeitis of the femorals, or lower with extension of the thrombus, until the abdominal aorta was reached. This, in the course of about seven days, began with pain in the extremities, coldness, numbness, loss of motion, blueness, swelling, distention of abdomen, and finally death. In the absence of an acute endocardial lesion with the formation of an embolus, it must be agreed that this was probably an acute infection. Although no etiological factor was demonstrated, the patient had a leucocytosis of 15,000. While this presupposed an infection, it cannot be so stated definitely.

The loss of motion in the legs may be accounted for purely by the loss of muscular nutrition, and thus the loss of tone; but recent experiments upon the ligation of the abdominal aorta in the dog, with changes in the lower spinal segments of the cord, may have been also active in this case.

The persistent abdominal distention is easily understood from the condition of the intestine. Here, putrefactive changes advanced rapidly, probably over the last three days, until the entire intestine was so friable that one could put the finger through the wall at any point. The extension of the thrombus to the arteries of supply of the abdominal parenchymatous organs resulted, not so much in a gangrene as in a nutritional necrosis.

Conclusions.—Clinically, an adult male in the course of a cardiorenal disease developed thrombosis of both lower extremities, probably as a result of infection. This produced, over a period of six

days, a complete thrombosis of the abdominal aorta, with gangrene of the body below the diaphragm.

Pathologically, the thrombosis probably began as an infectious thromboangeitis of both lower femorals, with extension of the thrombus until the abdominal aorta and all of its branches were involved.

VARIATION IN THE CHARACTER OF THE FOOD SUPPLY AS AFFECTED BY THE WAR.

By J. M W. KITCHEN, M.D., M S.,

EAST ORANGE, N. J.

It would seem as if medical attention to the issues of the war had so far been almost entirely directed to the matter of physical results of possible, and repair of, war injuries, and the influence of the septic and antiseptic conditions of camp life. There is another matter which should call for active interest and cooperative effort on the part of the medical profession; and that is the character of the food supply of the men at the front, and those who remain at home.

The present general interest in the prospective food supply of the world seems to be largely related to quantity. I imagine that the Germans more than any one else, are giving attention to quality. In this country the question of its quality should be an immediate matter of consideration to the medical world, and related conclusions be immediately formed so that educational influences can be promptly and generally diffused among consumers. Among Americans in the past, the matter of greatest interest has mostly been that of securing a supply of those food constituents that are most pleasing to the gustatory sense; but now we should consider the character of what we should eat.

In view of the world shortage of supply, perhaps the most important matter is to secure the greatest possible increase in wheat production and its distribution throughout the parts of the world where custom habitually calls for its consumption. In rendering help to the world we must consider that any radical change in dietary habits should be avoided as far as possible. This means that we Americans should be willing to give up a part of the wheat that we grow, for the benefit of others, and consume in place of what we give up, other foods.

One principle should be applied, which is that people of reduced incomes should eat less expensive foods and that food producers should produce more of the cheaper foods and not wastefully use those fundamentally valuable foods for producing high cost meat and other foods. Most people who can afford it eat too much meat with consequent autointoxicating effects from the putrefactive fermentations of proteins.

Of course our great American staple cheap food is Indian corn. It however is lacking in the same protein mysterious elements as are absent in wheat, vegetable oils and animal fats other than butter-fat. This lack in Indian corn can be made good by the addition of milk, butter-fat, eggs, and certain vegetables. Of course we know very little of the so-called vitamines other than that we know that unless present little or no animal growth can occur. Indian corn is somewhat irritating to the average alimentary structures. This trouble can be overcome by a considerable addition of rice or baked potatoes to the dietary, and to some extent by a long influence of heat and moisture in the preparation of the various food compounds in which Indian corn can be used.

Cow's milk is the cheapest source of animal food for man, and there is no better use for various pasture growths and the dried farm roughages than to turn them into butter-fat and milk. But very much more fluid milk is consumed than is good for the adult whose alimentary apparatus is in a state of development that will be benefited by a reasonable amount of work applied in digesting solid foods. The larger part of the milk produced should be turned into butter and dried skim milk powder, all of which if properly made are conservable foods. There is a considerable field for the use of beans as a dried food product, but we can learn considsiderable from the Chinese through the ways in which they utilize the soy bean by its preparation in various forms, through fermentation and otherwise, which not only improve its digestibility but also its gustatory character as a protein food. A great deal of food conservation can be done in the proper drying of garden-grown foods produced during the growing season, but to make this practical such conservation should be carried out in connection with drying plants established by communities, inasmuch as it is difficult if not impracticable to do much in drying foods by the individual domestic housekeeper. Among the dried foods of value, spinach may be mentioned because of its supposedly large content of vitamine principle. It is easily dried, and can be grown in large quantities during the coming fall, and as an undried product, throughout the winter in our Southern states.

A very important matter in the immediate future is the appointment of official experts in every county and town, whose function will be to diffuse information among the people as to what foods they should eat, and how to prepare them.

94 Prospect Street.

Uremia and Internal Secretions.—Remond and Minviele concluded as a result of special research that stimulation of the organs of internal secretion increases the normal resistance of the organism to uremic intoxication.—*La Presse Médicale.*

Syndrome of Avellis.—Laurens describes the results of a traumatism of the vagospinal nerve by shell explosion. This nerve is regarded by some anatomists as presiding over the movements of the soft palate. The result of the trauma was recurrent homonymous paralysis of the velum.—*Le Progrès Médical.*

Paroxysmal Vagotonia.—Danielopulo studied a group of young subjects who presented paroxysms of severe vertigo (occasionally with syncope), cerebral vomiting, and bradycardia. Uremia and meningitis could be excluded. The genuineness of the conception of vagotonia is shown by the fact that atropine acts favorably on the symptoms.—*La Riforma Medica.*

False Accusation of Rape and Spurious Pregnancy.—Tissier reports the case of a girl of seventeen who claimed to have been violated and impregnated. Her hymen was not only intact but formed a complete diaphragm in the vagina. A greatly enlarged uterus proved to be a hematometra with hematocolpos, the girl never having menstruated. The alleged rape consisted only of a superficial contact, evidently with the cooperation of the girl.—*La Presse Médicale.*

Military Medicine.

WAR FATIGUE.

(From Our Regular Correspondent.)

PARIS, June 11, 1917.

IN this communication I want to call to the attention of the civil practitioner certain conditions of mental and physical derangement rarely if ever met in civil practice and which will be among the earliest of his experiences if he is called to service in one of the front line hospitals. In the first place one does not have to be told that many a man carrying a gun, doing his assigned duty in the trenches and "going over the top" with a fixed bayonet at the sound of the whistle, in a charge upon the lines of the enemy, is wholly unfitted both mentally and physically to be a soldier. Mentally he is modest, shrinking, quiet, soft spoken; he may be an artist, a musician, some man's or woman's secretary. Physically he has never done any hard work in his life; he has lived in some quiet, sheltered place, from which he is suddenly called to the roughest sort of a life, often to sleep on the ground; good food but often indifferently prepared and not infrequently eaten at irregular intervals and sometimes after a long day of fatigue and waiting. One can readily understand that this man will soon break under the strain and be in the hospital; but a worse case than his is the strong man, mentally and physically, who disdains fatigue, danger, meals, and sleep; he often presents a condition of which I shall speak and which it is important that the newly arrived surgeon at the front line hospital should be prepared to meet. The manifestations presented in such a subject are all the more disquieting and pronounced for the reason that being a strong man he calls upon the last reserve of his will power to support the strain, unwilling to concede that he has arrived at, even surpassed, the limits of his strength.

Take a man (and only the best are sent there) who occupies the observation post ordinarily beyond the first line. During the twelve hours of his watch the post is under constant bombardment, and besides the unceasing alertness of his attention to his duty of watching every point where any movement of the enemy must be immediately reported by telephone, he is answering calls of the phone, noting the movement of aviators, the changing intensity of a cannonade; his nerves are at a constant tension not to be diverted from the attention to his duties by the roar of the cannon and the shells bursting around him.

Or consider a man in the advance salient of the trench watching for the expected onset of the enemy's charge, which is attempted and repulsed two or three times in succession during a few hours and he in the thick of it but unhurt. There are countless and one duties, conditions, and situations which put a man upon his mettle and call into play his every faculty, not for a moment, but for hours upon a stretch, which subject him to unusual and extraordinary mental strain which greatly accentuates his bodily fatigue. When this man reaches and surpasses the limits of his strength he often presents a condition and chain of symptoms calculated to mislead or puzzle the doctor at the *poste de secours*, but which is simply an exaggerated manifestation of fatigue.

The debut, sometimes sudden, is insidious; the subject complains of pains all over—in his head, back, legs, with frontal or occipital headache, rachialgia and myalgia, and always elevation of temperature, sometimes 101° to 102°. He has chills, coated tongue, and distaste for food, but demands drink. The headache is almost always accompanied by vertigo and roaring in the ears; the eyes may be bloodshot. The myalgia is most pronounced in the hips and legs and not infrequently the patient complains of pains in the joints. Nausea and sometimes vomiting are present.

The patient may have diarrhea, but is more often constipated. His pulse is accelerated and in keeping with the temperature, his face is haggard, and a hectic flush covers the cheeks. His eyes are brilliant and restless, or heavy, lusterless, and dead. Some give a history of or have epistaxis and sometimes vesicles appear upon the lips.

These symptoms last from three to six days. The temperature oscillates but, under the influence of a brisk purge (if constipated) and quinine, falls to normal, in the bad cases possibly to subnormal; but the pains in the bones and muscles persist and the patient is greatly fatigued or prostrated. This usually disappears, however, with rest.

The symptomatology makes the doctor think of grippe, pneumonia, typhoid, paratyphoid, rheumatism, or malaria.

Sometimes in spite of the abatement of the fever and other disquieting symptoms, the patient seems to lose strength. He complains of the continued pains in the lumbar region and legs and neuralgia all over. He complains of muscular asthenia and is without force or energy, to which may be added gastrointestinal atony.

There is no doubt but that most cases are the result of a considerable period of resistance and evolution in the course of which the continued exercise, physical, and mental fatigue have so depleted the functional vitality that the waste products are imperfectly eliminated and the subject is poisoned by autotoxins, which are doubtless active agents in the upsetting of the thermic equilibrium, producing the fever of fatigue, the professional malady of the soldier.

146 AVENUE DES CHAMPS ELYSÉES.

CASUALTIES IN THE MEDICAL SERVICE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—As you are aware, many various and extravagant figures have been published of the casualties in the Medical Service of the British Army. To obtain authoritative information in regard to these figures, I wrote to Colonel T. H. Goodwin, of the British Army Medical Service, who has been at the Western front since the war began until very recently, when he was detailed with the British Commission to the United States. He very kindly cabled the British War Office, asking for definite information, and obtained the following figures.

"The total casualties among medical officers of the British forces on the Western front from the

commencement of the war until the present date (June 25) are as follows:

Killed	195
Died of sickness	62
Wounded	707
Total	964

Total battle casualties (964 — 62) 902."

From these figures it is seen that only about 20 per cent. of the injured die. It is hardly necessary for me to add, for the information of our own medical profession who contemplate doing their bit, that these figures show the same relation between killed and injured as in our own estimated battle casualties, as given in the "Medical Service in Campaign," by Straub.

To encourage the volunteering of a greater number of medical men, who may have been deterred by the previous and widely published extravagant figures, I trust you will see your way to use the information supplied by Colonel Goodwin.

Robert H. Halsey, M.D.,
Captain, Officers' Reserve Corps, Medical Section.

CEREBRAL HEMORRHAGE DUE TO GAS POISONING.

Of all the horrors of the present war there is none which has impressed the popular mind with more vividness than the gas attack. And rightly so. It seemed when first launched upon an unsuspecting foe to be a fetid blast from the veritable mouth of hell. It swept over an army, and men curled up and died in agony, with all the miserable impotence of insects before the squirt-gun of the gardener. Those who survived lingered on in infernal torture for a few days, every breath a stab of pain, every moment an eon of anguish, and then gave up the ghost. But ere long the ingenuity of man found means to circumvent what it had invented; gas masks were devised and now cases of "gassing" are comparatively few.

Even so, the American surgeon, called to the front, should have no feeling of security in this regard. Gas attacks, while no longer so successful as at first, are still among the possibilities of civilized warfare and a thorough knowledge of the course, complications and treatment of a case of gas poisoning is indispensable. In this connection an article by Major F. W. Mott, a surgeon in the British army, is worthy of note (*British Medical Journal*, May 19, 1917). Dr. Mott calls attention to the occurrence of punctiform hemorrhages of the brain in gas poisoning, resembling those accompanying fatal cases of shell shock with burial. Some years ago this writer described the same sort of cerebral hemorrhages occurring in carbon monoxide poisoning incurred in the manufacture of nickel. Bignami and Nazari have described punctiform hemorrhages due to hyaline thrombosis of the small vessels of the white matter in such conditions as estivoautumnal malaria, apoplexy, and the diplococcal meningitis following pneumonia and measles.

Mott, after an exhaustive study of two brains of soldiers dead from gas poisoning, reports a number of curious circumstances. The white matter was peppered over with small dark spots about the size of a pin-head: these were due to hemorrhages. The red blood corpuscles were broken up and the hemoglobin converted into dark, chocolate-colored pigment granules which filled the capillaries, arterioles and venules of the white matter. Mott considered that the anatomical peculiarities of the vascular system of the cerebrum were responsible for these punctiform hemorrhages. The arteries terminate in the white matter and have each a separate capillary system, as have the emerging veins. this easily leads to stasis when there is any failure of the heart, or respiratory failure with right heart dilatation. These two factors may act separately or in combination.

Dr. Mott's observations are not only interesting in themselves, but they are of peculiar value at this time. The American army is entering a country new to it and meeting with perils to which it has hitherto been a stranger, any light which is thrown upon its way by those who have gone before it and any guide-posts which they may have erected are doubly welcome. They will prove added strands in the ties which are binding the two great Anglo-Saxon nations together in defense against a common foe.

The Soldier's Heart.—Professor Wenckerbach, who may be characterized as the Mackenzie of German-speaking peoples, delivered an address on this subject to military surgeons during 1916 which has been abstracted in *Il Policlinico*, March 4. There are two types of cardiac disease to be considered. The first comprises affections the existence of which is hardly open to doubt—organic essential diseases in the common sense of the term, such as lesions of the valves and orifices, cardiac musculature, pericardium, aorta, etc. The second type coincides largely with functional and symptomatic conditions, such as temporary dilatation, modifications of rhythm and subjective phenomena.

Lesions of the first type are, as a rule, readily recognized and military selection eliminates them from the category of soldiers' heart. While slight degrees of aortic and mitral insufficiency are occasionally encountered in which the most strenuous exertions are well tolerated, the general rule of exclusion should tolerate no exceptions because of the danger of an aggravation of the lesion or recurrence of endocarditis. When the state of the myocardium is in question the value of the heart's action must be carefully determined, and there is no form of diagnosis in which there are more sources of fallacy. Many symptoms such as arrhythmia, tachycardia, transitory dilatation, which were once attributed to the presence of a muscular lesion, have lost much of their supposed significance, especially in regard to arrhythmia. In order not to fall into error we must regard as certifiable myocarditic subjects only those who exhibit a notable hypertrophy of the heart, angiosclerosis and disturbances of the circulation of the lungs, liver, and kidneys. When such symptoms are absent the heart status had best be regarded as doubtful, demanding a special examination. It is enough that severe myocarditis is incompatible with good heart action and military service. Of affections of the—so to speak—cardiac appendages should be mentioned pericarditis, symphysis pericardii, severe aortitis, and aortic aneurysm. The recognition of these lesions

is often very difficult and the *x*-ray must be called upon before coming to a final opinion. Needless to say, subjects with this class of affections must be excluded from the army.

The doubtful group suggest above all complex states, made up of organic lesions, functional aberrations and even artifacts. Our diagnosis of this class of affections still shows many gaps and each case must be individualized. Take for example increased volume. To what extent is it evidence of disease? Since it is a natural consequence of valvular and orificial lesions and hence in this regard compensatory, it is not *per se* a disease, but a physiological reaction. Again, dilatation may cause enlargement of the heart without any element of hypertrophy. In the radiogram the two conditions appear alike. Again, the contour of the heart depends very largely on its position in the thorax, and this in turn upon the configuration of the diaphragm. A high diaphragm shows a larger heart and aorta. With a low-placed diaphgram we have a pendulous or drop heart with its typical elongation. This condition may be remedied by a retentive abdominal pad. Of great significance is the subject of the refilling of the heart. In diastole the latter must dilate, the two factors consisting of the duration of diastole and the quantity of blood which enters the heart. This latter factor is made up of an entire series of conditions—vascular and nerve tonus, the splanchnic circulation, the respiration, etc. Cardiac insufficiency means increase in volume as a result of diminished tonus of the myocardium; but other factors come into play here, for extrasystoles may be seen on the screen to augment the volume of the organ and this is also true of auricular fibrillation.

In the interest of simplicity percussion and palpation of the cardiac area must give way to radiography. The older methods reveal only the outline of the heart. A discrete hypertrophy of the left ventricle is very common, but of 47 out of 100 soldiers who presented this alteration only five were known to have actual lesions of the heart. Such a condition must therefore be grouped under normal variation in the absence of any evidence to the contrary. Even cases of drop heart should not be straightway excluded from milltary duty for all depends on the proper functioning of the diaphgram.

Unlike palpation and percussion auscultation can supply data of the greatest significance because murmurs have an independent value. Thus while diastolic murmurs often mean organic disease systolic murmurs often are heard in sound hearts. Functional pulmonic murmurs often deceive the general practitioner into the belief that he is dealing with organic disease. The significance of murmurs perceived in accelerated heart action in respect to functional incapacity must remain undecided because such murmurs may be heard in perfectly sound hearts.

The relations of arrhythmia to insufficiency must be carefully considered. We know today that normal hearts can beat without rhythm. Respiratory arrhythmia is a normal phenomenon. Extrasystoles in as far as they interrupt the heart's action may interfere with the circulation. Cases may occur in which they disqualify for military service. Heart block and auricular fibrillation are not necessarily hopeless because they can occur exceptionally as temporary phenomena. When permanent they naturally exclude from service.

Tachycardia may be simple or paroxysmal. The latter alone is pathological. In both forms the heart is insufficiently filled and when the alteration is permanent such hearts are insufficient for violent strains. Central vascular sclerosis revealed by simple resources, as accentuation of the second aortic sound, palpation of the carotids and radioscopy of the aorta. Soldiers with such handicaps can be employed in territorial service but are not equal to the fighting line.

Wenckebach is inclined to discredit the results of palpation of arteries and measurements of blood pressure. The danger is not from the peripheral, but from the central blood vessels. Subjects with tortuous temporal arteries are usually long lived. Subjects with severe cardiac lesions often present no objective symptoms, and those with angina pectoris may present no evidence whatever of cardiac or vascular disease.

Medical Transport Arrangements of the Navy.—James Porter and A. Vavasour Elder give an account of the method used for transportation of the sick and wounded of the Navy in the *British Medical Journal*, April 28, 1917, in which they state that the removal of these men from the scenes of their activities to the seclusion of a hospital is no small factor in the general work of the Medical Department of the Navy.

To deal with this phase of medical work a special medical transport organization has been created. There is a central office at the Admiralty for the principal medical transport officer, and thus in touch with the department. Medical transport officers have been appointed at all places around the coast where wounded are likely to be landed after action. At each of these places provision has been made for establishing dressing stations and temporary hospital accommodation for a certain number of cases until such time as an ambulance train can be sent to remove them to base hospitals elsewhere. One of the difficulties is the impossibility of arranging in advance or foretelling exactly at which spot and in what numbers wounded will be landed. Certain obvious bases exist to which ships return after an action, but at the same time these bases are far apart, leaving large gaps of coast line with many ports into which any one of which rescue vessels and smaller damaged vessels might be compelled to enter and discharge their wounded. Hence the establishment of what are termed emergency medical depots, with medical transport officers in charge of each at various places along the coast. Thus a sudden inrush of wounded men can be taken care of.

Briefly, from the time a wounded man is landed from a ship until he is finally placed in hospital, he is in the charge of the Land Medical Transport branch of the Naval Medical Service. The system adopted by the Navy differs from others in so far that when a man is wounded severely enough to require immediate treatment in bed, after having received medical attention, he is put to bed in his ship in a standard naval cot and made as comfortable as circumstances will permit. The cots are

canvas stretched over a wooden frame and laced together, and so made that the sides can lap over the wounded man, affording extra protection and warmth. Each cot is provided with sufficient bedding, including a mattress, thus making a complete bed wherever situated. These cots are "slung" to a standard, and are removable, so that from the time a patient is placed in a cot on board a fighting ship until he is finally put to bed in a hospital he is never moved out of it. He and his cot travel together all the way, thus saving much of the pain and suffering involved by frequent transfers by stretchers and trains. Ambulance trains, motor ambulances, bearer parties, etc., have been specially organized in a standard and uniform manner, with regard to each individual link of the transport chain. As regards the ambulances, beyond being fitted specially to take naval cots instead of the military stretcher, they are simply a squadron of thirty motor buses which were taken over from the London General Omnibus Company early in the war, and were fitted with spring trestles on which the cots rest. The writers state that these have proved exceedingly satisfactory in every way, being just as comfortable for patients as the latest pattern specially built ambulances.

Each emergency medical depot along the coast is supplied with cot, clothing, hospital, and medical units respectively. The cot unit consists of completely equipped service cots, which can be used to form the nucleus of a temporary hospital in suitable local buildings selected in advance for this purpose. The hospital and medical units contain all the necessaries their names indicate. The clothing unit is for use of men suffering from immersion and lack of clothing. In addition to preparedness for "The Day," the Medical Transport Department takes care of the ordinary sick from the fleet at the various ports. Ambulance trains take the sick and wounded each to his home port and in close touch with friends and relatives. No stops are made except for gas and water, or railway requirements as they arise. Each patient's dietary is carried out *en route*. A full-sized naval ambulance train carries 136 cots, and a smaller-sized train 40 cots and 36 sitting cases. All the trains are self-contained, and, when in motion, self-supporting, carrying everything in the way of provisions, stores, etc.

The staff consists of two medical officers and thirty-six men, including cooks, clerks, and others, who live in the train continuously. The trains are commissioned like ships, sea watches being kept day and night. For ordinary routine journeys, nursing sisters are not carried, but a cabin is set apart for two in each train for use when required, as after a naval engagement, or when any cases calling for their presence are being transported. The nursing itself is done, as in the navy afloat, by trained male sick berth ratings.

Porter and Elder tell of one of the interesting features known as the "Day Coach." These coaches are fitted with flap tables and the non-cot cases can sit at them. Under these tables is a row of wash basins connected with water supply. At one end of each of these coaches are two padded rooms fitted up for the more violent mental cases. A small dressing station supplied with instruments and drugs is also aboard. Very little is done in the way of dressings except while the train is at rest. For the same reason no operating theater has been arranged, on the assumption that a case in need of an operation would not be traveling. If such a case were encountered, operative measures would be carried out at the cot side, or the patient would be landed at the first opportunity.

A portable electric signaling device is fitted at each end of the train and coupled up with the engine, so that speed, heating, and other matters can be controlled. The trains are lighted by electricity —dynamo while running, and accumulator when at rest. Electric fans are fitted where requisite, and portable lights are arranged for in all the ward coaches. Gas is used for cooking only, and is carried under the kitchen cars and one car adjoining, the cylinders being coupled together; thus the danger of fire is reduced to a minimum. Heating of the coaches is by steam from the engine, carried in overhead pipes suspended from the roof. While running, the internal air current circulates the heat very evenly, and at the same time the floor space is clear of any obstacle which might get in the way of a bearer party while handling a cot. Sanitary arrangements are ample—about 10 per cent. of the carrying capacity of each train—and consist of water-sealed pans. Arrangements are made for "tapping" these while trains come to a halt for any length of time. Large storage capacity for water, domestic and sanitary, is supplied to each train. For administrative purposes a small office is fitted up centrally in the train, and contains typewriter, safe, and the usual office furniture.

Public Health Surgeons Detailed for Naval Service.—Seventeen surgeons of the United States Public Health Service have been detailed for duty with the Bureau of Medicine and Surgery of the Navy Department to assist in sanitation work, and twelve have reported for duty. The transfer was made at the request of Surgeon-General Braisted, in order to afford the Navy the services of these specialists as well as to relieve the regular naval surgeons for the special duties, which have been greatly increased by war demands. These surgeons will look after the sanitary arrangements of each naval district and general health conditions of the various camps and training stations where thousands of recruits have been sent, and to advise in regard to the sanitary arrangements of camps now under construction or to be built.

Available Emergency Ward Beds in Greater New York for Government War Purposes.—The Committee on Hospital and Medical Facilities of the Mayor's Committee on National Defense announces a summary of the number of emergency ward beds available in the hospitals of greater New York for Government purposes during the war. In the public wards there are 1431 beds in the male surgical wards, 395 in the female surgical, and 215 in the children's surgical, giving a total of 2041 beds; in the male medical wards there are 500 beds, in the female medical 386, and in the children's medical 1065, giving a total of 1951 beds. In the private general wards for men there are 1423 beds, in the women's 420 and in the children's 121, giving a total of 1964; in the medical division of the same wards there are 602 beds in the men's

wards, 291 in the women's, and 145 in the children's, giving a total of 1038 beds. In the private special wards for men there are 386 beds, in the women's 164, children's 714, none being available in the medical division of these last-named wards. The total number of beds thus far available for this purpose is 7708. Some of these beds are available immediately, while others are available on twenty-four hours' notice, on one week's notice, and on one month's notice.

Shortage of Professional Nurses.—New York City is facing a shortage of professional nurses, owing to the enormous number who have left or intend to leave for the front. The Committee on Nursing of the Mayor's Committee on National Defense is taking a census of all the nursing resources of the city, with a view to establishing a bureau through which all effective readjustments of trained and volunteer service can be made. Hospitals are being urged to increase the number of pupils on their rolls and to shorten their course for college women.

Red Cross Club in London.—The American Red Cross has taken a house in Grosvenor Place as a club for American nurses passing through London. The club will have sleeping accommodations, dining rooms, and an information bureau. A nurses' rest house in the country and hospital are the ambitions which it is hoped will soon be realized.

Antitoxin for War Gangrene.—The Rockefeller Institute for Medical Research through the research work of Dr. Carroll G. Bull and Miss Ida W. Pritchett, will undertake to supply the allied armies with a serum which is believed to be an effective antitoxin for the gas bacillus producing gangrene. Cultures of the gangrene bacillus were obtained in Europe last year and these investigators have experimented upon animals and produced the hoped for results.

New York Sends Ambulance Section to Camp.—The New York contingent of the United States Army Ambulance Corps is sending a section a week to the concentration and training camp at Allentown, Pa. These individual sections will consist of thirty-six men, non-commissioned officers, twenty-four ambulance drivers, mechanics, clerks, etc. It is expected that 100 sections of the United States Army Ambulance Corps will be among the first units to take up active service in France.

French Wounded to Be Treated in United States.—Quarantine stations all over the United States are rapidly being put into condition for the reception of the French sick and wounded, according to a report from Washington.

Navy Hospital Corps Almost Complete.—A little under a thousand men are now needed to complete the complement of 6116 required in the Regular Naval Establishment. There are now approximately 5200 in the corps, about 2000 of whom are in training in Hospital Corps schools. Arrangements are being made to place 300 members of the second class of the Naval Reserve Force in training at the School of Pharmacy of Columbia University, the facilities of which have been offered for use by that institution. A fourth Hospital Corps school is to be established at the new training station at Norfolk.

Government Rehabilitation of Maimed American Soldiers.—Rehabilitation of American soldiers who may be maimed or crippled in the war will be undertaken systematically by the Government. A conference of ten surgeons has laid before the General Medical Board of the Council of National Defence in Washington a plan for proceedings with this work through the agency of a permanent committee. War cripples are to be adapted to their old work if possible, or if so incapacitated, they are to be trained for new occupations for which they are mentally suited. Also the most modern mechanical apparatus for correcting physical defects should be made available as soon as possible for all disabled soldiers needing it. The conference recommended specifically the early training of medical officers in reeducation work; arrangement for treatment of the wounded by specialists as early as possible; the establishment of widely distributed reconstruction hospitals in this country, as far as possible adapting existing institutions to the work, supplemented by convalescent homes in country districts and similar places; arrangement for occupational analysis of the wounded; keeping the wounded under military discipline until the completion of physical reconstruction and reeducation in order to prevent their assenting through enfeebled will power to becoming dependent on relatives or the State for their support. The plan was drawn up by Drs. James Boardley, Jr., Baltimore, ophthalmology; John S. Davis, Baltimore, plastic surgery; C. R. Dooley, Pittsburgh, vocational education; S. L. Franz, Washington, neurophysiology; F. B. Gilbreth, Providence, management engineer; R. W. Lovett, Boston, orthopedic surgery; Harris P. Mosher, Boston, otology; T. H. Weisenburg, Philadelphia, neurology; W. A. White, Washington, psychiatry; Edwin W. Ryerson, Chicago, orthopedic surgery.

Appropriation Asked for Naval Hospital Construction.—President Wilson has sent to Congress the recommendation of the Secretary of the Navy for an appropriation of $2,200,000 for emergency hospital construction at points not now provided with hospitals or where hospital facilities are not suitable or sufficient for the needs of the Navy. Surg.-Gen. Braisted, in urging this appropriation, pointed out that the Medical Bureau's original estimate of $3,200,000 was reduced to $1,000,000 in the urgent deficiency act, and that the additional amount is required to meet pressing needs. He said that emergency hospital construction, now under way and approaching completion, at Portsmouth, N. H.; Newport, Philadelphia, Norfolk, Charleston, S. C.; Pensacola, New Orleans, and Great Lake will cost nearly $1,000,000 without equipment, and will therefore exhaust the present appropriation. Plans are being rapidly completed for temporary emergency hospital buildings at New York, Annapolis, Jamestown, Va.; Quantico, Va.; Key West, Great Lakes, Mare Island, and Puget Sound, which will cost about $1,800,000. In addition to those mentioned, other hospital buildings are necessary at Portsmouth, N. H.; Newport, and Norfolk, which will cost several hundred thousand dollars more. All the buildings mentioned as under way and contemplated are of an emergency type of construction and of a temporary character.

TRANSPLANTATION OF AN ECTOPIC EMBRYO.

ON May 2, 1916, the population of the United States became one greater than would have been the case without the performance of a most unusual operation about seven and one-half months previously. The operation consisted in the transplantation of an ectopic pregnancy from the Fallopian tube into the uterus, and was performed by Dr. C. J. Wallace of Duluth, Minnesota. While this feat, followed by the development and normal delivery of a healthy child at term, may have been accomplished before, we are not aware of it, and Wallace (*Surgery, Gynecology and Obstetrics*, May, 1917) was unable to learn of any similar case. As he says, heretofore it has been the advice of our best men that when ectopic pregnancy was diagnosed during the early quiescent period, or when it has been discovered during an abdominal operation, it should be removed at once. This has been the rule followed for many years, and has been accepted as the only thing to do. Discussing the development of tubal pregnancies, Wallace calls attention to the changes that take place in the uterus during the early months, the facts of especial importance being that "up to a certain point the uterus keeps pace with the tubal gestation, and actually forms a decidua, enlarges, softens, grows darker in color, and in fact takes on all the early features of pregnancy. It is playing the part of a disappointed hostess."

While stating that in some cases the removal of the tube and its contents will still be the proper thing to do, Wallace believes that sometimes, when we find an early case, when the tube is still in a healthy condition and not too distended, and all things are favorable, we should make a supreme attempt to save the life of the growing child by opening the tube carefully, dissecting out the embryonic mass intact, and transplanting it into the uterus. This, he says, can be very quickly done, does not endanger the life of the mother, and may be her only chance to bear a child.

This would seem merely a beautiful theory were it not for the fact that Wallace, in the course of an operation performed September 15, 1915, for uterine fibroid, found a tubal pregnancy, which he successfully transplanted into the cavity of the uterus through the incision employed for the removal of the fibroid. The tube was carefully opened and the mass dissected out intact, the operator being careful not to injure the sac in any way by keeping wide away and including part of the tube wall. It came out very easily, was about the size of a large olive, and was at once placed within the uterine cavity and caught by two of the sutures used in closing the deep wound in the uterus. The tube was closed by suture and left in place. Wallace felt that if the transplant failed to attach itself to the uterine wall it could easily be removed by the curette. Following this operation the patient was carefully watched for uterine hemorrhage or vaginal discharge, but no such symptoms occurred. At the end of two weeks the patient was discharged from the hospital, pregnancy went on normally to full term, and resulted in the natural birth of a fine boy, fully developed and without a scar, May 2, 1916.

Wallace expects that many such transplanted ectopic pregnancies will be reported in the future, and feels that while there may be failures in this as in other transplant operations, it is attended by little danger and is worth extreme effort in favorable cases. What constitutes the favorable case must, for the present, be left to the judgment of the individual surgeon.

OCCUPATION AND MORTALITY.

THE influence of occupation on the causation of disease and upon the rate of mortality has for long been a fruitful theme for medical writers. *Pari passu* with the progress of industrialism its ill effects on workers have increased. Perhaps, however, this is hardly a correct statement, for it must always be borne in mind that as industrialism has advanced so have methods for conserving the health of workers. There are, nevertheless, occupations in which to be engaged, despite all precautions, involves the risk of ill health.

In *Public Health Reports*, June 8, 1917, Drs. Shirley Wilmotte Wynne and William H. Guilfoy discuss the question of occupation in connection with the occurrence of certain diseases and the mortality therefrom. The conclusions drawn from the results of the investigations of the authors are, in brief, somewhat as follows: In the first place, the lack of data required for really satisfactory investigations is deplored as rendering the present method of studying the relation of occupations to mortality not really reliable.

Age, of course, has a most important bearing upon many diseases, and thus the number of persons at different ages in each occupation will affect the percentage of mortality caused by these diseases. One outstanding fact with regard to the mortality from respiratory diseases is that it is highest in those occupations which are carried on in crowded and poorly ventilated offices or shops.

and is especially high among clerks, bookkeepers, office assistants, compositors, and printers. An exception to the usual and to be expected state of affairs is the low mortality from pulmonary tuberculosis and pneumonia of garment makers. This apparently anomalous comparative immunity of these workers is attributed by the authors to a racial immunity, the majority of garment workers being Jews, who are supposed to be more or less immune, if not to pneumonia, at any rate to pulmonary tuberculosis.

There would appear to be some grounds for the belief that there is a relationship between cancer and occupation, inasmuch as the mortality from this disease is uniformly lower in the strenuous occupations and higher in the sedentary ones. This is a most interesting point, and certainly suggests further investigation in the same direction.

There seems to be an unduly high mortality from cardiac and renal diseases among cigarmakers and tobacco workers, and also among garment workers, which cannot be entirely explained by the advanced age of the workers in these occupations. Lobar pneumonia appears to be a risk in two classes of occupations; first, in those in which the workers are grouped together in shops and offices; secondly, in those occupations where the workers are exposed to continuous variations of temperature. With regard to suicide, only among cigarmakers and saloon keepers does the percentage rise above four.

The administrative measures suggested by these studiers are, in the opinion of the writers: first, a crusade against pulmonary tuberculosis and the respiratory diseases among clerks, compositors, and similar groups, and a more extensive study of the causes of the high mortality from pulmonary tuberculosis among teamsters and drivers; secondly, a widespread effort to control the incidence of heart disease among garment workers and cigarmakers, and in the third place, a campaign against the abuse of alcohol.

Although the writers of the paper confess that their method of tabulating the instances of the influence of occupation upon mortality is far from perfect, yet they feel that it is a long step in the right direction. Consequently, it is their intention to carry on their investigations, and in a subsequent report they hope to include all the principal occupations in which the people of New York City are engaged, and instead of limiting their study to the mortality of one calendar year to combine the statistics of death for a period of years in order that their tabulations may be less subject to frequent fluctuations due to the small number of deaths under observation.

INSECTS AND INFANTILE PARALYSIS.

It is somewhat extraordinary that it is only within the past twenty years or so that the conveyance of disease by means of insects has been demonstrated. It is true that in 1889, Theobald Smith found out the causative organism of Texas cattle fever, and that together with R. L. Kilbourne he showed that the organism was carried from Southern cattle to non-immune cattle by the so-called Southern cattle tick. Really, however, Manson was the pioneer in this field of research, for before the discovery made by Smith he had demonstrated the conveyance of the parasitic worm *Filaria nocturna* by mosquitos to man. The discovery that opened the eyes of scientific and medical men to the significance of insects in the transmission of disease was that of Ronald Ross and a number of the Italian investigators who found that malaria was carried by a species of mosquito.

L. O. Howard of the Bureau of Entomology, in his address as retiring president of the Washington Academy of Sciences, delivered on February 1, 1917, and published in the journal of the society, drew attention to the above facts, and in the course of his address gave his views with regard to the theory put forward by several scientific members of the medical profession that poliomyelitis was transmitted by insects. He pointed out that the entire country was interested and alarmed at the occurrence of an unusual number of cases of infantile paralysis during the past summer, and that many theories were advanced concerning its mode of transmission. He himself, when it was announced that the causative organism had been found in the intestinal passages, as well as elsewhere, and that it probably entered the body through the mucous membrane of the mouth and nose, instantly thought of the house fly and the all too frequent contamination of exposed food by this insect, frequently fresh from intestinal discharges. But second thoughts convinced him that were such a method of conveyance of the disease possible, the disease itself would be much more common.

Moreover, the not infrequent winter cases could not very well be fly-borne. Mosquitos have been suggested as carriers, and the rat flea has been laid under suspicion. But rat fleas go to human beings only in the event of epidemic disease among rats, and nothing of the sort has been observed in connection with any of the larger epidemics of poliomyelitis. Furthermore, in inoculation experiments reported by Flexner and Lewis, the virus was shown to be present in the blood in such high dilution that the infection in a normal animal was accomplished only by inoculation of 20 c.c. or more of the blood. If this holds good under normal conditions, it would be absurd to accuse any biting insect of conveying this particular disease, except in the possible event of the development of the organism in the body of the insect. While the possibility should be studied, the probabilities are against it.

The study of diseases carried by insects has opened an immense field of research, and one that has been assiduously cultivated, with results of incalculable benefit to the world. It is known that insects are responsible for the spread of many maladies, but not of all, and at the present time they are perhaps often unjustly accused.

THE PREVENTION OF MEASLES.

While the mortality from measles among the aborigines when once introduced among them is so high that whole communities are wiped out by it, the mortality among civilized communities, when complications are included, is not so far enough removed as to be creditable. Legislative enactments obliging notification and quarantine have been introduced nearly everywhere, but they have been varying in degree and enforcement in different communities. In any event it does not seem that either notification or quarantine has been effective in reducing the incidence of measles. There has been found no constant relation between legislation and the rise or fall of the epidemics. As health officers begin to awake to this fact they relax the enforcement or even the requirements of the law, but until there is more uniformity in the health laws regarding this disease no real judgment can be formed as to the value of notification and quarantine laws. What is needed is rather more uniformity in the laws than more drastic enactments. There must be a standardization fashioned after the most accepted methods.

There is no doubt that prevention of measles in epidemic proportions, at least, lies in early diagnosis and prompt isolation. The catarrhal stage is the most contagious stage because it is then that droplet infection is most likely to occur. But to be effective in prevention, diagnosis must be made in the pracatarrhal and in the preeruptive stage. Where there are large groups of children to handle, and even in the home, the only reliable means of control lies in the routine taking of temperatures, and the isolation of all children having temperatures above 99° F. When this procedure was introduced among the detained children at Ellis Island the incidence of measles, previously very large, immediately fell about one-half and has remained low ever since (Wilson, *Archives of Pediatrics*, April, 1917.) It would seem that an analogous procedure in schools, or even in homes, accomplished through the cooperation of physicians, parents, and health officers would materially reduce the morbidity from measles in a given community. Every rise in temperature in a child should mean isolation as completely as if that child were in fact afflicted with an acute contagious disease. Where home isolation is not possible hospital isolation must be carried out in the interest of the community. But here it must be admitted that the mortality from measles in hospitals is very high, higher even than in the homes, and no parent would be inclined to submit to this sacrifice in the interest of the community. This increase in the mortality, the likelihood to cross infection, and to complications is not inherent in hospital isolation, but is the result of the present faulty technique, faulty hospital construction, and careless attendants, as well as overcrowding and generally poor isolation facilities. Nevertheless, no matter how obtained, isolation is the only remedy for the measles epidemic.

The cubicle system of hospital isolation is the goal to be aimed at. Each patient should be completely walled off from the others, although the partitions can be made of glass to ameliorate somewhat the lonesomeness of the patients. In some European hospitals they believe that if infection from the droplet can be avoided measles patients can be treated in the general ward with only a wire screen between patients to remind attendants that there is a contagious case included within the screen—in short, for psychological reasons. This principle seems to be a rather radical departure in the present stage of our knowledge of the disease. But with the cubicle system other cases may also be taken into the ward without danger of infection provided technique and attendants are good.

In keeping with modern scientific aims for all disease conditions the aim in the prevention of measles would also be artificial immunization. The measles virus is contained in the blood at least twenty-four hours before the appearance of the exanthem and begins to fade about twenty-four hours thereafter. During this period monkeys have been successfully inoculated. Yet the period during which the virus can be found is very short and thus far experiments leading toward immunization have not been successful; but those are being carried on and there is hope that their success will add another triumph to preventive medicine.

THE HEALTH OF MUNITION WORKERS.

One of the mistakes made in England early in the war was in relation to the feverish energy in munition making. No effort was spared to produce a maximum output, and the ordinary laws of health for a time were disregarded. At many establishments work was continuous seven days in the week. This burning of the candle at both ends quickly resulted in a decline of output and a general deterioration of health, or rather the deterioration of health resulted in a decline of output. It became evident, as indeed it should have been evident from the first, that if the health of the workers were not guarded all resources could not be conserved, an essential point in the war of resources, and the highest level of production in the factories could not be maintained for a protracted period of time.

As Dr. J. W. Schereschewsky, Surgeon U. S. Public Health Service, writing in *Public Health Reports*, June 1, 1917, points out, it is entirely practicable to keep the health of the workers at an efficient point, and thus avoid the difficulty in which England found herself, by taking steps looking toward (1) the prevention of occupational diseases and poisonings, (2) the sanitation of work places, (3) the prevention of undue fatigue, especially important in the case of women and the young, (4)

the medical supervision of workers, and (5) the stimulation of industrial communities.

It goes without saying that the proper sanitation of work places is of vital importance. In factories in which munitions are made, or in which aeroplanes are manufactured, ventilating of a thorough character is a *sine qua non*, if health is to be preserved. Washing facilities must be provided on a wide scale, and lunch rooms on the premises with a supply of good wholesome food at a reasonable cost are desirable, and in most instances necessary, adjuncts of factories in which the handling of poisonous materials is involved. In England the supervision of the food of munition factory workers, and of women workers in particular, has been found to be absolutely necessary. If the meals of these workers are not thus supervised a large number, especially women, will eat inadequate and unnutritious food, with untoward consequences from all points of view.

The prevention of fatigue must be insisted upon, and the British experience has taught that one day's rest in seven is a necessity, and that not more than 56 hours weekly of heavy labor, 60 of moderately heavy work, and 64 of light labor can be endured for long without ill or disastrous effects.

This country can learn much with respect to the safeguarding of the health of its workers in munition factories and in establishments of a like nature, from the mistakes made by our Allies in the past.

Reestablishment of the Transparency of the Opaque Cornea.

Corneal opacity is extremely common, and often develops with great rapidity. It is very rare to see these opacities undergo involution. To see an opaque cornea clear up is an experience which makes a strong, unforgettable impression. Dr. Santos Fernandez, in the *Crónica Médico-Quirúrgica de la Habana* for June, calls attention to the fact that he has placed two such cases on record. Both occurred in children, of which the first had suffered from ordinary ophthalmia neonatorum, and the other from a purulent ophthalmia of unknown nature. Since that period his list of such cases has increased. In one adult the cornea, after total opacity, cleared up spontaneously. In six other cases the cornea, after total opacity, cleared up partially, and the establishment of an artificial pupil made a certain amount of vision possible. Much laboratory work has been done to determine the mechanism of corneal infiltration and opacity with a view of instituting some rational plan of treatment—thus far without success. Therapeutic measures can be employed only at the outset, during the stage of infiltration. Several Roumanian authors advocate the use of hot water applied directly to the cornea. There is also some reason for believing that in keratitis due to specific microorganisms some forms of antibacterial or antitoxic therapy will prove curative. A few paradoxical cases show either remarkable spontaneous involution or the occasional efficacy of simple antisepsis. The subject of preventing corneal infiltration by intensive treatment of the infection is of course quite distinct from that of treating an established condition.

Espundia and Blastomycosis.

Espundia is a special form of leishmaniasis with secondary manifestations in the nose and mouth which prevails in parts of South America and is due to the parasitism of the so-called American variety of the *Leishmania tropica*. For our knowledge of it we are indebted chiefly to Escomel of Peru (1911). The primary lesion (called chancre from analogy) is a cutaneous manifestation on some exposed portion of the body such as the dorsum pedis. The discovery was made that antimony given as tartar emetic by intravenous or intramuscular injection is a specific for the disease, suggesting the sterilizing action of its congener arsenic in spirillum and trypanosome disease. In the *Revista de la Asociación Medica Argentina* Escomel describes and illustrates cases of espundia and blastomycosis of the oronasal region. The resemblance in the photographs is considerable, enough to make diagnosis difficult in certain cases, especially since it has been learned that the two affections may coexist in the same subject. The treatment test is highly practical because antimony has no influence on blastomycosis. In a hybrid of the two affections the espundia component yields promptly to treatment, leaving the blastomycitic component intact. Escomel prefers the injection of Martindale's solution of antimonium oxide to tartar emetic as much less irritating. On the other hand, the latter is used in powder form as a dressing with great benefit.

News of the Week.

Medical Position Open.—The Municipal Civil Service Commission of New York City announces an examination for Chief Medical Examiner, open to all citizens of the United States, but persons accepting appointment must thereafter reside in the State of New York. The compensation proposed is $7,500 annually for full-time service, and candidates must be at least 30 years of age before the closing date for the receipt of applications. The incumbent of this position will be in charge of the office of the Chief Medical Examiner of New York City, and will perform the duties heretofore performed by the coroners of the various boroughs. Candidates must have a degree from an approved institution, and present evidence of having done, in an official connection, at least ten years' work in the pathological laboratory of a recognized medical school, hospital, asylum or public morgue, or in other corresponding official capacity. They must have performed at least 1000 autopsies. Special consideration will be given to administrative experience, preparation and presentation of evidence in court, and definite published contributions to the science of legal medicine. A graded examination will be given, and in the practical test an autopsy will have to be performed, with a report of findings handed in; candidates will appear before an examining board for the oral proof of personal qualifications.

Anthrax in Chinese Hair.—The source of an-

thrax cases in London has been traced by a local government board to shaving brushes made in great part of Chinese horsehair which had not been sterilized and was heavily infected with the anthrax germ. A consignment of shaving brushes from Japan was found to be heavily infected also with the same germ.

Dr. Simon Flexner of the Rockefeller Institute has been commissioned a Major of the Medical Reserve Corps, among 500 new officers of the Reserve Corps, United States Army.

Dr. Haven Emerson, Health Commissioner of New York, has been ordered to proceed to Fort Benjamin Harrison, Ind., and report to the commanding officer for a course of instruction preparatory to active duty in the Medical Reserve Corps.

Establishment of Fellowship.—The Women's Medical College of Philadelphia has established a Fellowship of $1,000 for advanced study in obstetrics for certain qualified women practising as specialists in this branch of medicine after benefit from the course.

Graduation of Doctors.—The University of Oregon graduated eleven candidates for the degree of doctor of medicine on June 10. Of these, four were graduated in absentia at the request of the Surgeon-General of the Navy, these men having been accepted as assistant surgeons in the Navy a month before graduation. The other graduates will serve as internes in hospitals, or will enter the Medical Officers' Reserve Corps of the Army or Navy.

Diazo Test Abandoned as Useless.—The New York Health Department has decided to discontinue the examinations of urine for the diazo reaction. This decision has been reached after the examinations of nearly seventeen hundred specimens of urine for this test during the past year in the Diagnostic Laboratory, of which less than 250 gave a positive reaction. The department considers that the time thus consumed with so little result can be more profitably employed, especially when, as at present, there are such heavy demands on the laboratory. No announcement has yet been made of the abandonment of the cancer-spreading biopsy examinations.

Help the Babies.—The New York Diet Kitchen Association has issued an appeal to the public for $10,000 to continue its work of saving the lives of the babies this summer. The full amount is needed, and the work is as important as any charitable work organized by the war needs. The association is now caring for over 2,500 babies by furnishing certified milk from their eight health stations, giving examination and advice through their physicians, and home care and inspection through their nurses.

Harlem Medical Association.—At a regular meeting of this association, held in New York on May 5, 1917, the following officers were elected: *President,* Dr. Sigmund Epstein; *Vice-President,* Dr. Thomas H. Cherry; *Secretary,* Dr. Louis Friedman; *Treasurer,* Dr. Gustave G. Fischlowitz; *Trustees,* Dr. Seymour Oppenheimer, Dr. Frederick P. Hammond, and Dr. John F. Connors.

Woman Honored.—Miss Grace Gasette of Chicago has been decorated with the cross of the Legion of Honor for services in the French hospitals. She has invented appliances for the treatment of difficult fractures.

Obituary Notes.—Dr. FERDINAND A. STILLINGS died at Concord, N. H., on June 22. He had practised in New Hampshire for more than forty years, and was a member of the United States board of pension examining surgeons for ten years; advisory surgeon to several hospitals, and for many years surgeon for the Boston & Maine Railroad, and medical director of the United Life and Accident Insurance Company. He served for one year as surgeon-general on the staff of Governor Hiram A. Tuttle and as a member of the State Senate. He was a fellow of the American College of Surgeons and a member of the American Medical Association, the National Society of Railway Surgeons, and the New Hampshire Medical Society.

Dr. CHARLES W. HOUGHTON died at Wynnewood, Pa., on June 5, at the age of 80 years. He was graduated from the Pennsylvania Medical College in the class of 1859, served during the Civil War as surgeon in the United States Army, was a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Montgomery County Medical Society.

Dr. EDWARD MICHAEL MCCABE of New Haven, Conn., a graduate of Yale University, School of Medicine, New Haven, Conn., in 1887, and a member of the American Medical Association, the Connecticut State Medical Society, and the New Haven County Medical Society, died at his home on June 5, aged 53 years.

Dr. ELIZABETH LOUISE ARTOIS HILTON of Brooklyn, N. Y., a graduate of the United States Medical College of New York in 1881, died at her home on June 14, aged 77 years.

Dr. CLYDE BARTLETT of Marion, Mass., a graduate of Boston University, School of Medicine, Boston, in 1915, died in Natick, Mass., on June 11, aged 34 years.

Dr. FELIX EDGAR BALBRIDGE of Huntsville, Ala., a graduate of the Medical Department of Tulane University of Louisiana in 1894, and a member of the Medical Association of the State of Alabama, the Madison County Medical Society, and the Southern Surgical and Gynecological Association, died on June 7, aged 50 years.

Dr. BURNSIDE FOSTER of St. Paul, Minn., a graduate of the Medical School of Harvard University, Boston, in 1886, and a member of the American Medical Association, the Minnesota State Medical Association, the Ramsey County Medical Society, the American Dermatological Association, and the Minnesota Dermatological Society, died on June 13, aged 55 years.

Dr. T. E. SAWYER of Uba, Tenn., a graduate of the University of Tennessee, College of Medicine, Memphis, in 1906, and a member of the Tennessee State Medical Association and the Weakley County Medical Society, died suddenly in Greenfield, Tenn., on June 7, aged 43 years.

Dr. CHARLES E. GILBERT of New York, a graduate of the New York Homeopathic Medical College in 1870, formerly chief surgeon of the Atlantic Yacht Club, died at his home on June 18, after a long illness, aged 68 years.

Dr. DALLAS M. TAYLOR of Amsterdam, N. Y., a graduate of Long Island College Hospital, Brooklyn, in 1874, died at his home about May 30.

Dr. WALTER A. MCCLURG of Washington, D. C., a

graduate of Jefferson Medical College of Philadelphia in 1872, a member of the American Medical Association and the Medical Society of the District of Columbia, and Medical Director in the United States Navy, retired, died at his home on June 15, aged 64 years.

Dr. JAMES BOURKE of Washington, D. C., a graduate of Rush Medical College, Chicago, in 1897, a member of the American Medical Association and the Michigan State Medical Society, and captain in the Marine Corps, U. S. Army, died in the Garfield Hospital, Washington, D. C., on June 17, aged 47 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

DEVELOPMENT OF BRITISH WAR SURGERY—AMBULANCE SERVICE—CASUALTY CLEARING STATIONS

LONDON, June 12, 1917.

THE developments of British surgery during the war attract much attention and are freely discussed wherever medical men meet. But at present it is only possible to record the more salient facts concerning the work of the expedition at the front. This has been done to some extent by regimental medical officers whose contributions have been received by some of our journals which show how carefully and rapidly the wounded are transported to the field ambulance sections in the support line. At this the first-aid dressings can be supplemented by various additions, the most important perhaps being suitable splints to secure an easier transit to the tent section of the ambulance, a mile or two further back. The surgical equipment of the ambulance has been greatly improved since the outbreak of the war and I am told that it is now ready at any time for the performance of any urgent operation. Only operations of this character should be undertaken in field ambulances, but to this statement the following exceptions must be allowed: (1) Completely smashed limbs should be removed, and the patients retained for at least a day before being sent to a casualty clearing station. (2) Hemorrhage should be arrested by ligature of bleeding points whenever possible; when not possible, plugging or direct pressure on the wound itself must be employed. Patients must never be sent down with tourniquets on their limbs. (3) Abdominal wounds and all severe cases demanding early treatment at a casualty clearing station should be sent there by a special motor ambulance direct from the advanced dressing station. They should not be kept waiting for the regular convoys. There being few good roads "corps dressing stations" were arranged by joining up some members of staffs of various field ambulances, so as to supply tent accommodation for a thousand or more wounded, with a staff of about thirty medical officers. This could do the duties devolving on separate field ambulances and was very successful as well as economical in medical officers and orderlies. It has been the supply of motor ambulances only that has made it possible to deal adequately with the surgery at the front. One aspect of this subject is often overlooked, viz., the use of motor transport in saving the wounded from capture, for it is certain that had motor ambulances been at hand in large numbers there would have been very few British prisoners after Mons and Le Cateau. In getting patients rapidly to the casualty clearing stations and also in saving wounded from falling into the hands of the enemy, motor transport has been of the greatest value, in fact the ambulance is the foundation on which the surgery of the front is based. No horsed vehicles could deal with the numbers resulting from a heavy fight unless they were so numerous as to block the roads for all other transport.

The development of the casualty clearing stations has been the chief factor in creating the new school of surgery at the front and it is said that they have assuredly saved thousands of lives. They were at first called "clearing hospitals" and were intended merely to clear the field ambulances and pass on the patients to the base hospitals. So their equipment was slight and their staff of eight officers less than that of a field ambulance. They carried 200 stretchers. These stations were soon overtaxed but became a nucleus around which an efficient organization for more complete surgical treatment could be established. Bedsteads and bedding were supplied and trained nurses appointed. The next addition was surgical equipment in the way of instruments and apparatus. The election of special surgeons followed and before the close of 1914 good surgical work was being carried on at eight centers. Progress continued from this time and by the end of 1916 more than 50 casualty clearing stations were at work. They were situated behind the line of trenches on the entire front. Every one must be at or near to a railway siding so that evacuation by train is easy; further they must be where good roads connect them with the front. Moreover they must have a good water supply. There are two series; (*a*) those nearest the front at a distance of 6 to 9 miles from the front trenches; (*b*) those in the second line which are from 3 to 6 miles further back and act as a reserve during active operations, or as units for special cases.

2. The Recognition of Pancreatic Insufficiency, with Special Reference to the Loewi Test.—H. Ryerson Decker bases his conclusions of the reaction of the Loewi test in pancreatic conditions on the results obtained in a series of 500 cases from the surgical and medical wards of the West Penn Hospital, Pittsburgh. The technique followed was that recommended by Loewi. Three drops of adrenalin chloride solution 1-1000 were instilled in one conjunctival sac, the other eye being used as control, and followed in five minutes by three more drops, the point being to fill the conjunctival sac. Dilatation of the pupil should occur within an hour if the test is positive. The amount of enlargement varies

from less than a millimeter to complete pupillary dilatation and occurs within a 15-minute period. The length of time taken for action seems to be dependent on the facility with which the adrenalin is absorbed, rather than on the amount used. Care is taken to exclude impaired or inflamed eyes. In the 500 cases, which covered a wide range of injury and diseases, there were 18 positive reactions, only 2 of which were known to have pancreatic lesion—one, a case of carcinoma of the pancreas, the other, chronic pancreatitis associated with gallstones. It might be of interest to note, on account of the etiological relationship which is thought to exist between gallbladder and pancreatic disease, that in 15 gallbladder cases there were 3 positive reactions. In only one of these was the pancreas involved. From this record it is apparent: (1) That the reaction is not pathognomonic of pancreatic disease, (2) that it is absent in cases which by other methods are proved to have pancreatic lesions. Whether or not in 6 of the 18 cases there was an associated pancreatic lesion it is impossible to tell without a doubt. At least, judging either by clinical history, physical examination, tests of the urine and stools, or intraabdominal examination at the time of operation, there was no definite evidence of pancreatic disturbance. On the basis of the present experience, then, Decker feels compelled to report the adrenalin test of doubtful diagnostic value. A test is yet to be found which will point out a pancreatic lesion early and surely enough to enable the surgeon or therapeutist to determine with a high degree of success.

8. Fatalities in Athletic Games and Deaths of Athletes. Robert E. Coughlin.

5. Constructive Suggestions Toward the Control of Measles, Scarlet Fever, Diphtheria, and Whooping Cough.—S. Josephine Baker points out that in New York the methods used at present in public health work show little or no change from those in vogue twenty years ago, as far as preventive work in the common diseases of childhood is concerned. The control of contagious diseases still starts with the reported case. This might be called "after the fact" work. Emphasis is placed upon limiting the spread of infection after the focus has already been discovered and represents almost the only purely corrective phase of public health work which persists at the present time. The preventive work which has been done in regard to the control of contagious diseases is mainly that which is associated with school medical inspection, and probably the avenue through which most future effort in this direction must come. Mortality, incidence and case tables in ten thousand population from 1906 to 1916 for New York City show a reduction in the incidence rate in diphtheria, scarlet fever, and measles, with a marked increase in the incidence rate of whooping cough. The mortality rate has varied but little for whooping cough, but the case fatality has decreased from 16.8 to 4.7 per cent. of reported cases. The mortality from diphtheria in ten thousand population has decreased from 4.5 to 1.8, while the case fatality from 12.9 to 7.6 per cent. of reported cases. In scarlet fever the reduction is from 1.2 to 0.2 and the case fatality percentage of reported cases has been reduced from 6.2 to 1.6. In measles the mortality reduction is from 2.75 to 0.87, but the case fatality percentage of reported cases shows but little deviation, ranging from 2.9 in 1906 to 2.2 in 1916. While it may be acknowledged that case fatality in these common infectious diseases of childhood is fairly low, still at certain age groups, notably in infancy, the mortality rate from whooping cough or from bronchopneumonia as a sequela of measles, is a serious menace to infant life. The sequelæ also must be considered. When one considers that scarlet fever is probably the most common cause of deafness, is it not significant that during 1914, of the total number of applicants for enlistment in the United States Army who were rejected for physical causes, the second highest cause of rejection, with a ratio of 89.97 per cent., was diseases of the ear, including defects of hearing, while the fourth highest cause was heart disease, with a ratio of 63.26 per cent. Surely, these two facts alone are significant. Baker considers that the same broad education of the public that has been employed in our efforts to control tuberculosis is needed in our child-welfare work. The public should be taught intelligently how to cooperate with existing authority for the control and prevention of the contagious diseases of childhood. Likewise the schools will in the future, as they have in the past, play an important rôle in the prevention of these diseases. A copy of the birth certificate is sent to every mother in New York City when the child's birth is registered; this certificate could be made to play an important part later on in life by, as Baker suggests, having recorded upon it the occurrence of any contagious disease or other important data relative to the child's physical or mental welfare. Thus isolation of the child whose certificate showed the occurrence of an infectious disease would thus be eliminated and lessen the amount of required supervision. Sanitary requirements in the home and elsewhere should be enforced. The Schick test for estimating immunization in diphtheria should be done on all school children. Since many of the most important infectious diseases are carried through nose and throat secretions personal hygiene should be taught in every community and attention given to teaching the proper use of the pocket handkerchief, and the possible danger from droplet infection from any unrestrained coughing or sneezing.

4. Hookworm Control in South China, Based on a Preliminary Study of the Incidence of Hookworm Infection in Hunan Province, China.—Edward H. Hume states that the problem of the control of this condition in South China differs in so many essentials from the same problem in America and other Western countries that its solution will require long planning by specialists and a persistently carried out program of practical endeavor. Stated briefly, the solution for Hunan and for all China, according to Hume, may be summed up in three words, survey, suppression and substitution. Under survey the extent of the problem must be determined, and the effect of the disease on the human economy gaged and compared with the effect of other animal parasites and bacterial infection. All difficulties to be overcome must be frankly recognized, such as ignorance, custom, lack of capacity for sustained effort, and financial stringency. Any new proposal may be regarded by the Chinese with suspicion for fear it will deprive them of their rights or do them harm. It is both financially profitable to market nightsoil and agriculturally indispensable to use human excrement for fertilization purposes in a land where horses and cows are few. Necessity is laid on the scientist and economist to conserve whatever he can of an ancient custom, at the same time that he seeks to eliminate the dangers. Since the Chinese seem incapable of long-sustained effort and most of the wealth is, as yet, largely

potential and underground, it follows that very little public money or even private wealth can be counted on for safeguarding the health of the community. Suppression of the disease can only come through education and isolation. Hookworm disease will disappear from China only when the method of substitution succeeds—substitution not of something else for human excrement as fertilizer, but of a nightsoil freed in some way of its danger, to take the place of one full of hookworm ova carried directly from the privy to the growing crop long before any process of fermentation has destroyed the ova therein. An attempt to make any organized investigation in a vast country like China is almost alarming. And yet, at a time like this, when the traders of the West are extending their commercial interests throughout China for the sake of profit to the citizens of their respective lands, is there not a call for unselfish service as well? Given such cooperation as the International Health Board has been able to extend to other countries, the local Chinese authorities will not be behind those of other nations in working both for the eradication of the hookworm menace and for a reform gradually of the entire system of sewage disposal, that is even more fundamental than the problem of mere hookworm infection.

2. The Leucocytes in Cases of Irritable Heart. Grace Briscoe.
3. The Influence of Maternal Oral Sepsis on the Fetus and Marasmic Children. E. Spencer Pierrepont.
4. The Vaginal Plug. E. Hastings Tweedy.

1. Goulstonian Lectures on Paratyphoid Infections.—This is the second lecture on this subject delivered by Charles Hewitt Miller before the Royal College of Physicians of London. Here the dysenteric type of infection is dealt with and Miller considers that the term dysentery is apt to be used too freely for conditions in which a painful diarrhea is the chief symptom. It should be limited clinically to those cases in which there is a frequent passage of blood and mucus accompanied by pain and tenesmus. Do the paratyphoid organisms cause dysentery? Of 310 cases from Gallipoli in Miller's series, 70 gave a history of dysentery, while in November bacillary dysentery became more common, the Shiga bacillus being more frequently found than the Flexner. Of the seventy cases of dysentery with paratyphoid stools, 58 of them began to be ill in the period of July to October—the amebic period. Amebiasis of the colon may be present without giving rise to any symptoms. It is possible that the symptoms may be begun and kept up by secondary infections such as the paratyphoids. There is no doubt, too, that the enteric organisms do attack the large intestine, and in Miller's opinion the paratyphoid organisms are even more prone to select the large intestine for attack. As a result of postmortem evidence it would seem that there can be ulceration of the colon caused by ameba or paratyphoid organisms without any symptoms of dysentery having been present; and that dysenteric ulceration may be caused either by ameba or paratyphoids A and B. Jaundice may appear early or later on in the course of the disease. It has a tendency to become recurrent, appearing after the patient has apparently been in good health for months after his illness, and may be very severe. Cholecystitis may occur and may be accompanied or not by jaundice. Acute nephritis is fairly common; it was present in 4 per cent. of Miller's cases. It was most commonly found in the period when "trench nephritis" was so prevalent. Albuminuria is usually present for a few days at the height of the fever. There is a great tendency for the paratyphoid organisms to find their way into the urinary tract. In several cases the organisms can be found in the urine both in the acute stage and afterwards for a varying length of time without there being any evidence of infection of the urinary tract. Some of the patients were admitted with the diagnosis of nephritis and the paratyphoid infection was discovered later. Cystitis is one of the commonest and most lasting troubles. The urinary tract seems to be very susceptible to the *B. paratyphosus B.* In these cases Miller has found that urotropine has decidedly beneficial action, and approves of a routine use of this drug in all paratyphoid fevers both for prevention and cure of urinary infections. Two conditions of socalled rheumatism developed, acute articular rheumatism and more commonly a condition more closely resembling the "infective" type of arthritis. A third group was classed as the "trench fever type." Diseases of the respiratory tract are common in paratyphoid conditions. Paratyphoid fever may be regarded as a great imitator of other diseases. Further, it has the quality in certain individuals of being able to call into activity diseases which were lying latent.

3. The Influence of Maternal Oral Sepsis on the Fetus and Marasmic Children.—E. Spencer Pierrepont considers that at a time like the present, when the children of the British Empire are such an imperial necessity and asset to the nation, it is the aim of every medical man to do all in his power to enable those children to be as healthy and vigorous as possible, therefore he calls attention to a condition of maternal oral sepsis and its resulting evils upon the children that has not received any attention from the medical world before the present investigations were undertaken. For the past nine years Pierrepont has kept observations upon marasmic children and their mothers, and also those children who, being breast fed, yet suffered from diarrhea and vomiting, and the conditions of the mothers' mouths carefully noted. All the cases examined, and of which notes were made, were first examined by physicians as to their condition and then referred to the author as being more or less obscure and about whom nothing definite was known. He gives detailed illustrations of some of the cases. In some cases the mother may herself acquire a certain amount of immunity by antibodies from her own toxins and that would explain the birth of certain healthy and vigorous children in spite of the maternal oral sepsis. Stress is laid upon the term oral sepsis, as certain of the mothers' mouths showed the teeth to be well formed, free from caries, and with all the teeth *in situ.* In many cases where the mother had several children there was found a progressively increasing change for the worse in the health and vigor of the younger children of a greater degree of intensity than one would expect to find as the result of repeated pregnancies, suggesting other agencies at work than the natural exhaustion of the mother, and explicable on the ground of a successively increasing toxemia. The conclusions drawn from a series of some 500 cases, from which the above 20 cases are a fair selection, are: (1) The toxins from the maternal oral sepsis have a very strong influence in a large number of cases upon the vitality of the rapidly growing fetus, so that the child is handicapped from before birth with a lowered vitality, and therefore the marasmic condition is antenatal in its inception. (2) That prematurity of birth and miscarriages, where no other cause can be discovered, are brought about by the toxic state of the mother induced by the septic condition of her mouth. (3) The diminution in the quantity, or alteration in the quality, of the mother's milk, where no other cause can be ascertained, is due to the selective affinity of certain toxins for certain secretory cells of the mammæ, and where no such diminution or alteration can be demonstrated, then the toxins, and in some cases microorganism themselves, are in the milk. (4) In the toxemias of pregnancy and the puerperium the high pressure at which the emunctory organs are working is probably adversely influenced by the toxic state produced by the mouth, and this is the deciding factor in many cases that just brings the balance down on the wrong side and results in eclampsia or the other toxemic conditions. It is interesting to observe that in two cases where the mother had had marasmic children immediately before the last-born child, after the mother's mouth had been treated the next pregnancy resulted in a healthy child and no marasmus has supervened.

5. The Method of Spread of Gas Gangrene into Living Muscle. J. W. McNee and J. Shaw Dunn.
6. The Successful Conservative Treatment of Early Gas Gangrene in Limbs by the Resection of Infected Muscles. C. H. S. Frankau, Hamilton Drummond and G. E. Neligan.

5. The Method of Spread of Gas Gangrene into Living Muscle.—J. W. McNee and J. Shaw Dunn state that in their experience gas gangrene is essentially a muscle disease and they have never seen it commence where injury of muscle could be excluded, the primary focis in every instance being in damaged muscular tissue. No example of gas gangrene beginning in and remaining localized to the subcutaneous tissue has been met with, and a condition spreading below the skin which is met with in base hospitals would appear to merit some special investigation before a relationship to the general type of gas gangrene can be established. Clinically, the rapidity of spread of gas gangrene into living muscle, once the disease has begun, is so remarkable as to demand some definite explanation such as has been sought for by histological methods and here suggested. The earliest case of gas gangrene examined histologically showed the condition already established three and a half hours after the wound was received, and they have seen massive gas gangrene of a limb lead to a fatal issue twelve hours after a wound of the thigh. A point to be noticed is that death may occur quickly, following a comparatively slight wound, when examination postmortem shows gas gangrene involving only a small bulk of actual muscle tissue. The material elaborated by the bacilli, whether it be a true toxin or not, is a powerful systemic poison. Anthony Bowlby has pointed out that cases of this kind may very readily be mistaken for death from shock alone. Wounds involving main blood vessels allow rapid development of gas gangrene in distal segments or parts. The spread of gas gangrene into healthy, living muscle, with an intact blood supply is a less easy problem. Two factors must be brought to mind: one is the clinical observation, now well established by the microscope, that gas gangrene tends to spread in the longitudinal axis of the muscles, so that single muscles are involved from end to end while neighboring ones are untouched. Fresh material is absolutely essential for correct conclusive investigation as the organisms proliferate and produce gas rapidly in the warm body after death. Amputated limbs and stumps left after amputation afford good material for examination as anaerobic organisms are found in the healthy muscle at a considerable distance from the actual seat of the gangrene, but their presence does not constitute gas gangrene. The *Bacillus aerogenes capsulatus* (*B. perfringens*) is the commonest and most abundant organism present in this condition. By the examination of serial sections of tissue, most of the information has been obtained by the method of spread. Macroscopically this spreading margin is sometimes fairly sharp, at other times, somewhat irregular. The muscle fibers at the margin are paler and duller than the normal but the color change is little more than might be accounted for by total absence of blood in the part involved. The outer limit of the process while indefinite can be mapped out fairly closely if the healthy tissue beyond is still contractile, as this power is lost in the part becoming gangrenous. At the advancing edge the muscle is firmer to the touch than the healthy fibers beyond and the firmness is found in the gangrenous part behind. Microscopically in a section taken from as near as possible the advancing edge, various changes are found. Various normal fibers are seen, while others exhibit a striking change. The staining reaction is different, and dots indicate the individual fibrils lost. The fibers are swollen, but are well separated from the interstitial connective tissue, to leave what appears to be a clear space. The fiber still shows the uniform eosin tint indicative of degeneration. The sarcolemmal nuclei still stain brightly. What determines the advancing death of the fibers? The writers, after thorough experimentation, have decided that the spaces between the fibers and the interstitial connective tissue are filled with a toxic fluid which spreads along the interstitial tissue and the fibers, killing the latter as it advances. Once the fibers are killed the anaerobic bacilli live on them, breaking down the sugars and producing gas in abundance. With regard to the route followed by these organisms, these are, at the spreading edge, never found in the fibers themselves, but are practically confined to the reticulum. After the fibers are broken down the organisms invade them in numbers. Fewer germs are found in this completely degenerated tissue, only gas, and they travel to the spreading zone. In rapidly spreading gas gangrene leucocytes are generally absent in the involved muscular tissue. The rapidity of the spread may account for this as leucocytes take time for development. McNee and Dunn conclude that the rapidity of spread of gas gangrene into living voluntary muscle is so remarkable as to require explanation by a different process from that which governs ordinary septic invasion of tissues. It is suggested that the facts are accounted for by the peculiar anatomical structure of muscular tissue; as the sheaths inclosing the long individual fibers are so easily detachable as to form potential spaces into which toxic material can readily pass, causing necrosis of the fibers. The early selective invasion of single muscles is consistent with the above view.

La Presse Médicale.

March 29, 1917.

Prophylaxis of Infection of Projectile Wounds.—Vincent has already called attention to the practicability of the immediate disinfection of recent wounds at the front. The measures recommended by him and carried out in his own service have testified to the soundness of his views. Mere aseptic dressings favor infection, for both aerobes and unaerobes can flourish under this shelter for days or until the base is reached. Microorganisms breed with extraordinary rapidity under these conditions, the tissues being macerated and imbued with blood. When these wounds are first exposed a reddish serum is seen to exude which gives off a bad odor. The patient has temperature and the surgeon must at once proceed to excise the entire wound area. Such excision may be quite too late to prevent gas gangrene, and in the end the limb must be amputated. As is known to many, the author has long recommended primary disinfection of wounds with calcium hypochloride. This treatment is both simple and efficacious and applicable almost anywhere save in penetrating wounds of the thorax and abdomen. The author adds boric acid to the extent of one-tenth, and the mixture is especially active against the *B. perfringens* and its associates. In fighting on a huge scale when the wounded come in by thousands this application is especially adapted for wholesale use. The author recommends the dry dressing exclusively.

Results of Examination of the Blood After Wounds.—Govaert calls attention to the asthenic syndrome seen in the badly wounded with the unusual fall of blood pressure. This state is due to shock, hemorrhage and sepsis. Of the three, hemorrhage is the most readily eliminated. Injection of artificial serum also has a most favorable influence on shock. But if serum cannot bring back the tension, transfusion must be thought of. It is in this connection that blood tests may prove of value. Before tests can be made we must learn the effect on the various elements of the blood of the status of severe wounds. Research shows us that for the first 3 or 4 post-traumatic days the number of erythrocytes steadily diminishes. Equilibrium is reached and held for 2 or 3 days, after which there begins a slow increase which may transcend the normal. In other words, hyperglobulia may develop, and this even after a severe hemorrhage. In a subject who lost his arm in a shell explosion the erythrocytes fell from 4,800,000 to 2,780,000, then rose to 4,700,000 shortly before death. The increase was very sudden, and while hyperglobulia did not develop, the case was of that type. In a case of perforative appendicitis the author saw the red cells go to 6,350,000. Such a phenomenon has no good prognostic significance, and seems to signify only the development of peritonitis in the course of an injury or disease. In regard to the leucocytes most wounded develop a marked leucocytosis. It disappears rapidly, has no apparent connection with inflammation or toxin

production and may be termed simply traumatic leucocytosis. The author attempts to draw some practical conclusions from these finds but they only confirm that which was already known and which could have been learned in their absence. A sudden rise in the number of red cells or a hyperglobulia would suggest peritonitis or perhaps a transudation in one of the largest serous sacs. A marked leucocytosis after injury could suggest an internal hemorrhage, etc., etc.

La Presse Médicale.

April 2, 1917.

The Specific Serum Treatment (Prophylaxis) of Infected Wounds.—Leclainche and Vallée conceived the idea of a local serum treatment of wounds as long ago as 1912 and memorialized it before the Academy of Sciences. The matter was tested in both the clinic and laboratory, and three years later, with the war in full swing, the subject was brought up before the Academy of Medicine. It should be stated that long before the subject was agitated of a serotherapy of wounds in man, veterinaries had pursued the idea of a serotherapy or serovaccination against wounds in horses. One of the authors (Vallée) is Director of the National Veterinary College at Alfort, and experiments in this province go back to 1897. The method of the authors consists in the use of specific polyvalent sera in the form of dressings or hypodermic injections. The former stands in no relation whatever to ordinary serotherapy nor to the local use of lymphagogue substances, etc. It involves the use of a polyvalent serum which in the hands of the Bazyo, Quénu and others has given excellent results. According to the latter it checks suppuration and promotes epidermisation. But one must be eclectic in this field because in the case of some particular germ a good antiseptic does best—for example, a weak nitrate of silver solution is the best antagonist of the *Bacillus pyocyaneus*. Injections of the polyvalent serum have been used much more generally and the injections and dressing have been used in association. Thus far no anaphylaxis or other accident has been reported. But although these preparations seem to have been discussed favorably by the Academy of Medicine and the Hospital Society and have been prepared and authorized under Government control, we nowhere find any detail as to content, manufacture and standardization. The serum is, however, readily obtainable in packages accompanied by full directions.

Dehydration of the Blood and Organs in Diabetic Coma.—Chauffard, Le Conte and Dorie, as a result of actual research into diabetic coma show that progressive dehydration is in evidence The skin is flaccid, the eye hypotonic, the blood pressure low. After death the water content of the viscera is readily seen to be lessened. the kidneys and pancreas leading in this respect. The entire process is toxic, an acid intoxication or acidosis. The ketone bodies gain entrance to the cerebrospinal fluid and can act directly on the cortex. In certain autopsies the odor of acetone is very strong when the cranial vault is opened. The toxic bodies which play the chief rôle are by no means all known, and collectively must represent a considerable number of substances varying with the case. Venesection in diabetic coma shows that the blood is unduly viscous and thickened. There are, therefore, two leading indications for treatment. First, the blood must be rehydrated, and second, antitoxic substances—alkalies in this case—must be administered. The two indications can be filled together by the infusion of a solution of sodium carbonate by the intravenous route, enteroclysis and hypodermoclysis. The concentration is of vital importance—say from 15 to 20 gm. of soda for each litre of water.

Le Progrès Médical.

May 5, 1917.

Propathies of Tuberculosis.—Raymond states that when a young man begins to cough and lose flesh his mother will demand of the physician a positive or negative diagnosis by no means easily made. "Suspicious bronchitis" is often as far as he cares to go. Doubtless he could go further if he utilized all possible resources. There are not a few diseases which are known to act as forerunners of tuberculosis, and when a youth presents himself with one of these the physician should invariably examine the chest. These affections are due presumably to the toxins of tuberculosis, and represent a "cry of the organism for a richer blood." The entire subject can be studied to advantage among young soldiers. As far back as 1882 Peter called attention to sciatica as a propathy of pulmonary consumption, and his work has since been regarded as a classic of medicine. The present author has seen this association several times. In a soldier of 42 left-sided sciatica appeared and persisted for 9 months before patient developed a dry cough. The *x*-ray showed a faint shadow in the left apex, with corroborative physical signs. In a second case, in a soldier, the sciatica preceded the pulmonary symptoms over two years. In a third case the interval was very brief. Other cases are mentioned. The sciatica was in some soldiers severe enough to cause their evacuation from the ranks, and to make necessary a hospital sojourn. One patient, on the other hand, was known to be tuberculous when his sciatica appeared, and in the other cases the age of the tuberculous process could only be surmised but was evidently by no means recent. In other words, in sciatica of this type the tuberculous lesions should already coexist else there could be no place for the genesis of the toxins. Herpes zoster has been regarded as a possible propathy of consumption since 1878 (Leudet) and there exists a small literature on the subject. Whenever this disease attacks a young subject his chest should be *x*-rayed. The author has recently seen a case in a soldier. Psoriasis, usually a disease of the robust, is said by Gaucher to indicate occasionally the presence of a tuberculous focus. The relationship here is open to some doubt but several cases are given in one of which sciatica, psoriasis, and incipient pulmonary tuberculosis coexisted. The author also mentions erythema nodosum as a propathy, but this coincidence is sufficiently well known.

Correspondenz-Blatt für Schweizer Aerzte.

March 31, 1917.

Gastropexy for Gastroptosis. — Bircher writes at length on the operation originally conceived and executed by his father in 1891 for gastric dilatation. At a later period it was learned that no sharp distinction could be made between dilatation and prolapse, the actual condition for surgical intervention being gastrocoloptosis. Interventions which have been directed against this condition comprise colectomy, gastrectomy, gastroplication, gastropexy, omentopexy, and gastroenterostomy, the last named being pronounced contraindicated. The original Bircher operation was a gastroplication, an operation which has since been done freely by others, including Beyea of the United States. The end results are said by the author to be somewhat disappointing. Omentopexy or Coffey's operation gives a better outcome but is inferior to gastropexy. The last named intervention has been practiced chiefly by Rovsing of Copenhagen, Duret of Lille and the author. Duret's material is not given. Rovsing and some of his Scandinavian colleagues have performed gastropexy no less than 256 times while the author has a record of 62 operations. The percentage of cures is nearly two-thirds of the entire number, or 204 cases. The Scandinavian operative mortality is nearly 5 per cent. while the author lost but one of his 62 patients. The cases marked "improved" agree in the two series —about 20 per cent. The per cent of unimproved was 9.6 in the author's series and 12.8 in the Scandinavian series. The author gives Rovsing credit for the technique which he has somewhat modified. The fixation sutures pass around the costal arch or just beneath it through the skin. Three sutures parallel with the lesser curvature traverse the serosa and muscularis as far as the pylorus. At a distance of 3 or 4 cm. from the puncture these sutures are brought through to the left of the laparatomy wound and knotted over a glass drain. It is not, of course, to be understood that these 318 operations were all undertaken for uncomplicated gastrocolopexy. Other operative conditions were associated at times but no details are given beyond the statement that in 6 of the author's 62 cases gastric ulcer was present.

Book Reviews.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics, Materia Medica, and Diagnosis in the Jefferson Medical College, Philadelphia. Assisted by LEIGHTON F. APPLEMAN, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. Price, $6.00 per annum. Philadelphia and New York: Lea & Febiger, March 1, 1917.

THIS number of Progressive Medicine contains articles on Surgery of the head and neck, by C. H. Frazier; Surgery of the thorax, excluding diseases of the breast, by G. P. Müller; Infectious diseases, including acute rheumatism, croupous pneumonia, and influenza, by J. Rühran; Diseases of children, by F. M. Crandall, and Rhinology, laryngology and otology, by G. M. Coates. Most of these articles are by old and tried contributors; but we notice one new name, that of Dr. G. M. Coates. As was to be expected, there is a lengthy article on Poliomyelitis; much that has been written on the subject is reviewed here, and perhaps in another year we may be able to read what has actually been accomplished in the early diagnosis and treatment of this disease.

STUDY OF ORGAN INFERIORITY AND ITS PSYCHICAL COMPENSATION. A Contribution to Clinical Medicine. By Dr. ALFRED ADLER of Vienna. Authorized translation by SMITH ELY JELLIFFE, M.D. Nervous and Mental Diseases Monograph Series, No. 24. Price, $1.50 net. New York: The Nervous & Mental Disease Publishing Company, 1917.

THIS book is really an introduction to the author's "Neurotic Constitution," which should be read in connection with it. His thesis is that neurotic traits of character have their origin in certain very definite defects of organs. These he has demonstrated by actual anatomical and physiological investigations. These deficiencies may be converted to an extraordinary development of the organ, *e.g.* the stuttering boy, Demosthenes, became the greatest orator of Greece. As a rule, however, the phenomenon of organ inferiority is reflected on the psyche in such a manner that its whole structure has a peculiar impression. The psychical structure thus obtained becomes a foundation for neuroses and psychoses. One little known discovery of his is that external stigmata often mean inferiority of segmentally related internal organs, a "segmental insufficiency." Adler's views are, to say the least, original and while he is of the Freudian school, he perhaps will not offend the rabid opponents of those doctrines because he finds a physical basis for psychical symptoms, even though the connection be not at once apparent. Jelliffe is to be congratulated on his very readable translation of Adler's horrible German. The book is well gotten up, except for the lack of an index and the paper binding.

A MANUAL OF PHARMACOLOGY AND ITS APPLICATIONS TO THERAPEUTICS AND TOXICOLOGY. By TORALD SOLLMANN, M.D., Professor of Pharmacology and Materia Medica in the School of Medicine of Western Reserve University, Cleveland. Illustrated. Price, $4.50. Philadelphia and London: W. B. Saunders Company, 1917.

A LABORATORY GUIDE IN PHARMACOLOGY. By TORALD SOLLMANN, M.D., Professor of Pharmacology and Materia Medica in the School of Medicine of Western Reserve University, Cleveland. Illustrated. Price, $2.50. Philadelphia and London: W. B. Saunders Company, 1917.

WHEN the first edition of this work appeared some fifteen years ago it was at once recognized as a distinct advance on the books on materia medica which had hitherto been available. For the first time the physician found himself in possession of a book in which the action of drugs was based almost entirely upon animal experimentation, and in which well directed research replaced casual and often haphazard observation. The student found, too, that the study of drugs could only be satisfactorily accomplished when it was placed on a scientific basis, and when materia medica had its laboratory and experimental work just as physiology and chemistry did.

The two handsome volumes now before us are the second edition of Doctor Sollmann's book. But the revision has been so extensive and so thorough that the result may well be considered as a new work. The author has done well to divide the book. The physician will find in the larger of the two volumes all that he needs on the action of drugs. In some respects the work is encyclopedic in its fullness of detail; but in many cases, particularly where the drugs are of slight importance, the information is of the briefest. Important features of the work are the constant reference to the labors of other writers and experimenters and the carefully selected bibliography. The laboratory manual contains a large number of exercises, carefully arranged and divided into two sections. In the first part the exercises are confined strictly to the bare essentials needed by students who intend to become general practitioners of medicine. The second part is of a more advanced character, and deals with animal experimentation; it also shows the response of animal tissues and organs to various pharmacological agents. The volumes are well printed, and the work will appeal to all who are in any way interested in the modern (or scientific) methods of practising medicine.

THE HISTORY OF THE PSYCHOANALYTIC MOVEMENT. By Prof. Dr. SIGMUND FREUD, LL.D., of Vienna. Authorized English translation by A. A. BRILL, Ph.B., M.D., Lecturer in Psychoanalysis and Abnormal Psychology, New York University; former Chief of Clinic of Psychiatry, Columbia University. Nervous and Mental Diseases Monograph Series, No. 25. Price, 60 cents net. New York: The Nervous & Mental Disease Publishing Company, 1917.

SUCH a spectacular movement as psychoanalysis had to have its historian, and who more fitted for the task than its founder, Professor Freud? In the present little volume he has faithfully traced psychoanalysis from its vague beginnings when Brever and Freud treated their patient, since become famous, up through its stages of uncertainty, apathy, hostility, and recognition. He mentions his various pupils, disciples, and opponents, and tells of the schisms which took place from time to time, on the whole quite fairly. In his accounts of Jung and Adler, for example, he exhibits commendable restraint. Both the followers and the opponents of this movement will find much of interest in this little book.

THE STARVATION TREATMENT OF DIABETES, with a Series of Graduated Diets. By LEWIS WEBB HILL, M.D., Junior Assistant Visiting Physician, Children's Hospital, Boston, and RENA S. ECKMAN, Dietitian, Massachusetts General Hospital, Boston. With an Introduction by RICHARD C. CABOT, M.D. Third Edition. Price, $1.00. Boston: W. M. Leonard, 1917.

THIS new edition of Hill and Eckman's aid to the treatment of diabetes has been somewhat enlarged by the addition of the anaylses of some of the more important diabetic foods. The series of graduated diets also has been revised, chiefly by the reduction in the amount of fat content. In other respects the volume is much the same as in the previous editions. The Allen treatment has definitely proved its worth in the difficult problem of the treatment of diabetes and the satisfactory prosecution of the treatment can be reached only when the patient is possessed of at least much of the information which is to be found in this book. It is probably not too much to say that every diabetic should own and study this book and many physicians can profit by its use.

AN INQUIRY INTO THE PRINCIPLES OF TREATMENT OF BROKEN LIMBS. A Philosophico-Surgical Essay with Surgical Notes. By WILLIAM F. FLUHRER, M.D., Consulting Surgeon to Bellevue and Mount Sinai Hospitals. Price, $3.00. New York: Rebman Company. 1917.

DR. FLUHRER has long been an authority on the subject of the treatment of fractures and has been a pioneer, so far as devising methods for rendering such treatment effective from all points of view is concerned. This volume clearly expounds the principles of treatment best calculated in the author's opinion to be productive of good results. The work is highly instructive.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-second Annual Meeting, Held in Atlantic City, May 2 and 3, 1917.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. GEORGE DOCK OF ST. LOUIS, IN THE CHAIR.

Wednesday, May 2—First Day.

The President's Address.—Dr. GEORGE DOCK of St. Louis delivered this address. He said that many objections had been made on similar occasions regarding the size of the membership and with 50 candidates for active membership and about one-fifth as many vacancies it seemed to him that this was the time for a renewal of the discussion. Beginning with a membership limit of 100 they had now in thirty-one years reached a total of 215 members—147 active, 25 associate, 34 emeritus and 9 honorary. After considering the methods for increasing the membership he cited some of the objections to an increase, and referred to the work of the German Kongress für Innere Medicin, which had its beginning four years before this Association. With fewer medical schools in the Teutonic countries there were many more great hospitals with expert medical staffs fitted for and contributing to medical advance. In 1914, before the war, the membership was 706 and attendance 737. The suggestion was offered that the line of advance should consist in ending the associate membership by not taking on new members and dropping all now on the list who were either not active or no longer eligible; next, by withdrawing pressure on active members to become emeritus; and finally by raising the present limit of membership to the original standard of admission. There was no need for their consideration of many questions that properly came before the American Medical Association. But he asked if they could remain aloof from certain great social questions as they had in the past. With the upheaval of standards and methods in all lines of human activity with the excitement of passions and loss of calmness that activated all great political disturbances there would be the demand for the exact training and cool judgment that such a body as theirs represented. Could they refuse either as individuals, or as a body, to act or go on record when they saw or heard the call for assistance? He thought not. Very recently such a call came and at the proper time they would have the opportunity of considering what action was to be taken.

Dr. Dock then read a letter from a member of the Council of National Defense in which he asked that members of the Association offer their services to the United States Government and to inform it of the best capacity in which they could serve. Due stress was laid upon the comparatively small membership. By next year as many as possible should be prepared for service in both the Army and Navy. It was suggested that the members of the Association could render great service as consultants. The capacity of the hospitals should be increased to meet the demands.

Dr. WILLIAM H. WELSH of Baltimore said that this subject had been considered by the proper authorities and that the Surgeon General of the Army had spoken to him of the vital importance of speeding up and graduating students, for which the speaker thought at present there was practically no need. There was no necessity for such hasty action. It was not necessary either that the medical schools should take students during the summer.

Studies of Digestion.—Dr. FRANK W. WHITE of Boston read this paper, in which he considered the following:

(*A*) *Effects of Stimuli from the Lower Bowel on the Rate of Emptying the Stomach:* In some persons with partial obstruction in the ileocecal region the stomach emptied very slowly, without any lesion of the stomach being found at operation. Experiments on animals showed that when the colon was strongly irritated by injections the stomach retained food much beyond normal limits. Evidently a strong stimulus from the bowel was needed to slow the human stomach, for it was found that the stomach emptied within the normal five or six hours, in some cases with ileal stasis of two or more days' duration, and in most cases with good-sized twelve-hour residue in the ileum, and also when the colon was distended by a large enema.

(*B*) *The Effect of Massage on the Colon:* Cannon's method of direct examination of the bowel and the *x*-ray was used in studying the human colon at intervals after giving abdominal massage (especially of the colon). There was great variation in different persons in the accessibility of parts of the colon to massage. Vigorous massage usually mashed up the contents of the colon, but had little or no immediate effect in moving the contents forward. When a full cecum was apparently emptied at once it was found that gas had moved forward and solid contents merely flattened out in both directions. Massage sometimes delayed but usually hastened the passage of colon contents at the end of several hours, evidently by stimulation of slow peristalsis. The effect of this stimulus was small in comparison with the stimulus of taking food. A rapid onward "mass movement" of a large portion of colon contents was seen very rarely (twice) after massage. These large movements had no direct relation to the force of massage, but followed gentle palpation.

Dr. S. J. MELTZER of New York asked about the reflexes. The retardation might be caused in two ways. First, by inhibiting the movements of the stomach walls and, second, by increasing the contraction of the pylorus. In the first they would have an arrested progress in the gastrointestinal canal. That it might increase the contraction of the pylorus would not be surprising because they knew that by obstruction in the gastrointestinal canal the peristalsis was increased as the action of the sphincter would also be increased.

Dr. FRANKLIN W. WHITE of Boston said that it seemed to him that there was no doubt that the delay was due to spasm of the pylorus and not to any inhibitive action of the stomach.

The Importance of Duodenal Alimentation in Severe Dyspepsia Occurring after Gastroenterostomy.—Dr. MAX EINHORN of New York reported ten cases of postoperative severe dyspepsia treated by duodenal alimentation. Two were described in detail and eight in tabulated form. Of these, eight made good recoveries, while two necessitated renewed surgical intervention. These patients were thoroughly examined to ascertain if the pylorus and gastroenterostomy openings were patent. If such patients were placed on duodenal alimentation for two weeks one was apt to get good results.

Dr. JULIUS FRIEDENWALD of Baltimore believed this to be a life saving method of treatment and said he had used it in a great number of cases. After the operation of gastroenterostomy the patient was not cured, or cured only for a short time. In several instances duodenal feeding had helped him out and he recalled one case in particular. This was a man, 23 years old, with an ulcer of the stomach treated medically and the condition was relieved for a short time only. Gastroenterostomy was then done and the patient was relieved for about six months, when he had a return of his symptoms of ulcer of the stomach. Duodenal feeding was then resorted to and he had now been well for nearly two years. He thought this method should be tried further before operations were undertaken.

Dr. CHARLES G. STOCKTON of Buffalo said that his results corresponded very closely to those of Dr. Einhorn's. Some patients suffered after operation with symptoms of what he described as a "vicious circle" and the patients after operation were sometimes worse than they were before; in these patients the food passed from one opening out and back to the stomach through the other. He was convinced that he had seen at least one case relieved of symptoms after the use of the duodenal tube.

Dr. FRANKLIN W. WHITE of Boston said he had used the duodenal tube in two cases. There were some instances in which the tube did not work well.

Observations on Intestinal Bacteria in Children.—Drs. WILLIAM WEBBER FORD, K. D. BLACKFAN, and M. D. BATCHELOR of Baltimore presented this paper, which was read by Dr. Ford. He said that during the past

three years an attempt had been made to discover changes in the bacterial flora of children as a result of feeding them with artificial foods, particularly protein milk. The stools of breast-fed children reveal small Gram-negative bacilli, small Gram-positive bacilli and micrococci, and large Gram-positive bacilli. Cultures on plain and dextrose-agar gave only Gram-negative bacilli, *Bacillus coli* and *Bacillus lactis ærogenes*. The small Gram-positive cocci and bacilli could be obtained by transferring material to acid broth. They were aciduric organisms (*B. acidophilus*, etc.). The large Gram-positive bacilli were ærobic spore bearers and could be obtained only by heating material to 85° C. and incubating for twenty-four hours. Artificially fed children had shown the same types of Gram-negative organisms, the same small Gram-positive micrococci and bacilli, but in addition a great profusion of large Gram-positive bacilli. The authors believed that these organisms were definitely increased in certain conditions, particularly by the use of special articles of diet.

Observations on the Treatment of Myelocytic Leucemia by Radium. — Dr. Herbert Ziegler Giffin of Rochester, Minn., reported thirty patients with myelocytic leucemia treated by means of the direct application of radium element over the spleen. The effect of the general condition of the patient, the size of the spleen, hemorrhages, and the blood pictures was entered into, as well as the reaction and the radium burns. In the method used he made applications with 5 to 10 mgs. of radium in a tube for from three to four hours, with a total exposure of twenty-four to thirty-six hours. A belt that was used for protection against radium burns was described and presented. A combination of the proper treatment with exposures to radium seemed to him to be the best treatment for myelocytic leucemia.

Dr. Alfred Stengel of Philadelphia reported his experience with the *x*-ray treatment in leucocytic leucemia. His experience with the treatment with radium was practically nil. The number of cases he had treated with the *x*-ray was in the neighborhood of fifty and the records that were available were forty-two. In many of these cases the clinical improvement was far out of proportion to that of the blood condition. More of the cases had eventually better results clinically than those cases in which the improvement in the blood picture was noted. Leucocytic leucemia like pernicious anemia seemed to be a relapsing disease. He suggested this as a possible end result in treating cases of leucemia. They had had a number of patients who lived four or five years, perhaps six years; eight years was the maximum duration of life.

Dr. Francis W. Peabody of Cambridge, Mass., said at the Huntingdon Hospital their results had been as Dr. Giffin had described. There was a remarkable drop to the normal of the white count and a decrease in the size of the spleen. It seemed to him that these cases should be followed up with great care; they should return for examination once every week or once every month. Some only returned when the symptoms appeared again. When they returned as a rule the spleen was enlarged and the blood count was very great. At present they had one case that had been under observation for a period of four years, and he was apparently in very good condition. In every case that showed evidences of being cured they tried to keep the blood count down as nearly as possible to the normal. These cases appeared to be perfectly well if their blood count was kept between 20,000 and 30,000. So soon as the blood count rose and the spleen enlarged then further treatment was definitely indicated. He had little opportunity of comparing the effects of the *x*-ray and radium. They had had one or two cases where the treatment by the *x*-ray had no beneficial effects. He was not convinced, however, that the *x*-ray was used in a satisfactory manner.

Dr. Leonard G. Rountree of Baltimore asked what experience the members had had with the acute type of leucemia. He reported the case of a girl who gave a brief five or six weeks' history of her trouble. She was anemic and had an enlarged spleen. She was given a transfusion and applications of radium were made. She died at the end of ten days. An exposure of the radium for twenty-four hours had no effect on the spleen, probably because she did not live long enough. He asked if any present had had any experience with this combined type of therapy; also if any had had any experience with the relapses that occurred, and whether they could get the disease under control by specific treatment. Had any tried the injections of the soluble radium salts? It seemed to him that such treatment restored the bone marrow to a great extent.

Dr. Lewellys Franklin Barker of Baltimore referred to some practical studies from the theoretical side. One wondered if the mass of bone marrow cells originated in the marrow and collected in depots, or did they arise from other tissues. He rather favored the view that this condition existed all over the body. Fatty bone marrow only developed the cells. The pathogenesis was very obscure. One thought of some abnormal stimulus, some primitive stimulus. If this were true then they were dealing with a tissue disease and not a bone marrow disease. There was a stimlating effect with a tendency to proliferate; if so, how could radium do good? It destroyed a great many cells. Was the destruction of the cells limited to the spleen where applied, or was it diffuse over the body? Of course they were treating the whole of the symptoms rather than the disease itself. They should consider all the accessory factors that could be of help in the therapy of the disease.

Dr. William S. Thayer of Baltimore agreed with what was said in regard to the relapses in this disease. He always regarded this disease as related to pernicious anemia. There was, too, its spontaneous disappearance under the old fashioned treatment by arsenic.

Dr. S. Solis Cohen of Philadelphia said he had the opportunity of observing the results from both kinds of treatments, and it seemed to him that radium was more prompt in getting results and without much constitutional reaction. In his experience the combination of radiation with arsenic, as suggested by Morton of New York, was followed by the longest prolongation of life and with the greatest amelioration of the symptoms.

Dr. Joseph Almarin Capps of Chicago said that the *x*-ray and radium destroyed some substances which were poor in the leucemic cells. These substances were more or less selective.

Dr. Herbert Ziegler Giffin of Rochester, Minn., was glad to hear Dr. Peabody state that it was better to keep the patient in good general condition than to reduce the leucemic count to a low point, not above 50,000. He did not use arsenic until after he had used radium. These cases relapsed. One should consider the intravenous injection of soluble radium salts, but so far they had not attempted them.

Lung Ventilation.—Dr. C. F. Hoover of Cleveland, Ohio, presented this paper. He said that the respiratory excursion of the upper thorax was characteristically modified in the following conditions as shown by clinical and experimental studies: (*a*) When the scaleni were paralyzed; (*b*) when the intercostal muscles were paralyzed; (*c*) when extensibility of the upper lobes were impaired. Respiratory excursions of the lower thoracic cage gave valuable information: (*a*) on the total lung volume; (*b*) the degree of obliteration and the degree of distention of the pleural sinus; (*c*) the relative enlargement of the left and right ventricles of the heart; (*d*) the total enlargement of the heart; (*e*) enlargement of the pericardial sac; (*f*) paralysis of the intercostal muscles, paralysis of the diaphragm; (*g*) differentiation between paralysis of the diaphragm and activation of the diaphragm without excursion of the leaf of the diaphragm; (*h*) the size of the respiratory unit; (*i*) an explanation of the error of Duchenne's interpretation of the diaphragm which had been accepted at the present time.

Dr. A. Jacobi of New York said that Dr. Hoover had alluded to the upper portion of the thorax, but premature ossification of the upper part of the thorax should be considered which resulted in narrowing the upper part of the thorax, giving rise possibly to tuberculosis and emphysema. A number of operations had been performed for such an emphysema. He was glad that Dr. Hoover was doing work along this line.

The Significance of the Percentage of Carbon Dioxide in the Alveolar Air in Pneumonia Patients Who Were Cyanotic.—Dr. R. D. Pearce of Cleveland, Ohio, presented this communication, which was read by Dr. Pearce. He said it was possible to calculate the capacity of the dead space and the percentage of CO_2 in the alveolar air by comparing the percentage of CO_2 in ex-

pirations of varying depths, following a normal inspiration. The mathematics depend upon the influence which the dead space air exerts as a diluting agent in reducing the percentage of the CO_2 in expirations of different amounts. The method was very accurate and could be easily carried out in untrained subjects by the use of an apparatus which made the taking of samples practically automatic. The CO_2 pressure in the alveolar air was found to be lower than normal in some cases suffering with fibrinous pneumonia. In these cases cyanosis was present, but there was no evidence of cardiac impairment, air hunger or acidosis. Patients with massive pneumonia who had no cyanosis had a normal or high percentage of CO_2 in the alveolar air. The capacity of the dead space in both conditions was less than was expected. An explanation of this phenomena might be found in the assumption that the pulmonary circulation continued through the consolidated lung after its respiratory function had failed. This condition would supply venous blood to the left heart, which, acting as a diluting agent to the arterial blood, would increase the tension of carbon dioxide and decrease the tension of oxygen in the arterial blood. The increase tension of CO_2 in the blood stimulated the respiratory center with the result that the minute volume of the respiration was increased and the percentage of CO_2 in the alveolar air was reduced. The blood passing through the healthy lung had a lower than normal content of CO_2 to compensate for the high content of CO_2 in the venous blood with which it was mixed in the left heart. However, since the blood which passed through the healthy lung was fully saturated with oxygen no compensatory mechanism could be established by which the oxygen content in the mixed blood in the left heart could be brought to a normal oxygen tension. The blood therefore appeared cyanotic. The condition was somewhat analogous to that found in congenital heart disease.

Dr. C. H. Hoover of Cleveland, Ohio, asked how much blood was going through the pulmonary circulation and how much in the consolidated area and other parts of the lung that were encroached upon. How much unrespired blood was poured into the left ventricle?

Dr. Samuel J. Meltzer of New York described a method by which the blueness of the blood might be made to disappear by the administration of oxygen in these cases.

Clinical and Pathological Features of Bronchiectasis.—Dr. Alfred Stengel of Philadelphia read this paper. There were sixty-three cases reported, thirty-six cylindrical, eighteen sacculated, and nine cylindrical and saccular. There were two cases, cylindrical, of tumor obstructing treachea or bronchia. One case, cylindrical, of tumor metastasis in the lungs. There was one case of aneurysm, cylindrical and sacculated. Doubtful, five cases, one cylindrical, three sacculated, and one cylindrical and sacculated. There were nine cases of broncholiths, seven cylindrical and two cylindrical and sacculated. Of the pneumonias, there were, croupous one, bronchopneumonia eight, fibrinous eight, a total of seventeen, twelve cylindrical and five sacculated. There were twenty-seven tuberculous cases, twelve cylindrical, ten sacculated, and five cylindrical and sacculated. There was one case of atelectasic, cylindrical. The cylindrical and generalized bronchiectasis were amenable to medical treatment. He referred particularly to the special methods of treatment of this condition—first, the postural. This combined with the use of the vaccines resulted in benefit. Second, the specific types seen clinically. The most important sign associated with respiration was the "trapdoor" breathing, a condition he failed to see described in the current literature. Some called it the "veiled puff." Third, the treatment of the condition of emphysematous signs in the upper lobe. The upper lobes were very frequently involved, but the lower lobes were more frequently the seat of the disease.

Gastric Polyposis.—Drs. J. Friedenwald and John Miller Turpin Finney of Baltimore presented this paper which was read by Dr. Friedenwald. He reported three cases of this affection, and in both operation was performed and the condition demonstrated. In both instances carcinomatous degeneration was noted. A review of the histories of both cases, together with the *x*-ray examination and gastric findings pointed toward cancer. The third case was demonstrated by a specimen and presented a most marked instance of polyadenoma gastrica. The underlying cause of adenopapillomata was a chronic gastritis. In some cases the symptoms were very severe.

Dr. William S. Thayer of Baltimore said that some twenty-five years ago he was very much interested in one case. The patient was a lady, sixty or seventy years old, who presented the symptoms of pyloric obstruction. She vomited continuously. She had a large dilated stomach and a distinctly palpable tumor. No examination of the gastric juice was made, but the symptoms and signs pointed clearly to a case of pyloric obstruction. No metastasis could be made out. At autopsy there was found a long pedicle which engaged the pylorus and caused almost a complete obstruction. The microscopical examination did not show any evidences of carcinoma at all.

Dr. Theodore C. Janeway of Baltimore said he had seen an interesting type of that condition at St. Luke's Hospital which showed particularly the great motility of the tumor which lay between the ensiform and the right iliac region, but it never was on two consecutive days in the same portion of the abdomen. The symptoms and signs were those of carcinoma of the stomach. At autopsy there was found a pedunculated adenocarcinoma of the stomach which hung by a very long pedicle.

Alimentary Hyperglycemia Following the Repeated Ingestion of Glucose.—Drs. L. Hamman and I. Hirschman presented this report, which was read by Dr. Hamman. He concluded that the first injection of glucose stimulated while the second injection caused a less marked degree of hyperglycemia. The levulose was affected less than the glucose.

Dr. H. O. Mosenthal of Baltimore said that the practical bearing if translated into a normal diet was that there was not much rice sugar; as a matter of fact that was what was found in determining the blood sugar after a meal.

The Present Outlook of Diabetic Treatment.—Dr. Frederick Madison Allen of New York said that he had looked over a large amount of material in the hospital and tried to learn if it was possible to differentiate between the presence of diabetes and its absence. In cancer, pancreatitis, arteriosclerosis, and some other diseases various peculiar islands were found microscopically in both the diabetic and the non-diabetic material. It seemed impossible to establish diabetic disease. The sugar tolerance had never been tested. Some patients died with symptoms of diabetes and yet the islands that were there could have been saved by proper treatment; if the islands were not there recovery could not take place. If the diabetic could not be diagnosed at necropsy from simply a scarcity of islands the bulk of evidence lay with the clinician rather than with the pathologist. What was the interpretation? The failure to find the islands might be explained by animal experiments. In animal experimentation where the change was marked the condition ran a short course. It generally took months and years to bring the islands to a state of disappearance. If the disease was slower it was hard to find the islands in the human as they were found in experimental animals. The discharge of specific internal secretion was more rapid than the cells could form it and produced an exhaustion of the cells. In the worst type the treatment sent the patient into acute coma. Keep feeding the patient up to the point of tolerance to warn off acute dangers such as threaten. These patients might come to necropsy with little islands left. Inflammation of the pancreas had produced diabetes experimentally. There was a hardening of the pancreas and the islands were softer, caused by a loss of resisting power. With proper technique the pancreas became fibrous and not like the soft normal pancreas. It was noteworthy that in pancreatic inflammation without impairment or degeneration of the thyroid, the inflammation of the thyroid could be cleared up by diabetes. If they were dealing with traumatic diabetes the treatment could be instituted early and a radical and practical treatment was indicated. Diabetes was a weakness in assimilating food due to insufficient secretion of the islands. In going over the records for the past three years they collected thirty cases and these records were not bad. The present method was not a time saving device, but resulted in a greater prolongation of life. The islands were vital organs and should not be broken down. Progress should

be sought in some remedy to make good the organic defect.

The Maintenance Diet in Diabetes Mellitus.—Dr. HERMAN O. MOSENTHAL of Baltimore read this paper. He said that during the past few years, thanks principally to the efforts of F. M. Allen, the problems in the feeding of cases of diabetes mellitus had been very much simplified. By eliminating the carbohydrate element from the diet and lowering the protein and fat content of the food to an extent never before thought feasible the urine had in nearly all instances been rendered sugar free. The acidosis previously regarded as a dangerous factor, when such a dietary was ordered, had usually been readily controlled by limiting the intake of fat. The temptation at the present time lay in underfeeding these patients, thus rendering them free from glycosuria and acidosis and their attending dangers, but paying very little attention to the nutrition of the individual. It would seem self-evident that the body could not endure a loss of its muscular and glandular tissues over an indefinite period. A diet inadequate in covering the needs of the body in these respects would express itself in a negative nitrogen balance. In the present studies an attempt had been made to determine what constituted a maintenance diet in diabetes mellitus as measured by this standard. Carbohydrates were eliminated from the diets except as contained in the green vegetables. It was found that in order to furnish food which was palatable over a long period it was not possible to reduce the number of grams of fat much below those of protein. The nitrogen balance was determined on a series of diabetic patients under these dietary conditions. It was found that in an average individual a nitrogen balance could be obtained on a carbohydrate-free diet of 1,500 to 1,700 calories. The practical conclusion to be drawn from these observations was that every diabetic patient who was treated by means of a carbohydrate-free diet in which the number of grams of fat and protein were approximately equal to one another should ingest at least between 1,600 and 2,000 calories of this food in order to insure a nitrogen equilibrium—that was, a maintenance diet. When the glucose tolerance of the patient had warranted it the diet when increased beyond 1,690 calories in small individuals, or 2,000 in larger persons, had usually been augmented by the addition of starch-containing food and not by further protein and fat.

Diabetes in Children.—Drs. E. P. JOSLIN and HORACE GRAY of Boston presented this communication, which was read by Dr. Joslin. A series of 123 cases of diabetes in children under the age of fifteen years were analyzed especially as regards etiology, improvement in prognosis, and treatment. When one considered diabetes in children the question arose whether they should be as pessimistic as to the outcome as had hitherto been the case. Some 53 cases under the age of ten years had come under his supervision. Of these 31 were dead and 15 living in one group; there were 7 more cases, 2 dead and 5 living, making an average duration of over five years. Of the 5 living cases, they have gone on eight or nine years and appear to be in good condition and sugar-free. The cases either living or dead up to this time averaged 1.1 years; during 1916 the average duration was 1.6 years. Obesity played an important part in the etiology of diabetes in adults, 40 per cent. of his cases showing it. Among the children he had been impressed with one case which he thought was the type of a great many. This child showed sugar when four years old. At the age of one year he practically had the weight of a child of one year. At one and a half years he weighed what a child of two years weighed. Then he had a serious infection and the child was put to bed until the temperature subsided. This child was well fed and was given milk from a Jersey cow. At two years he weighed what a child of three and a half should weigh and at two and a half years weighed what a child of four years should weigh. With a twelfth infection—mumps—sugar appeared in the urine. The lack of exercise, overfeeding and the infections had much to do in bringing this on.

The Association Between Diabetes Mellitus and Tuberculosis.—Dr. S. SOLIS COHEN of Philadelphia said that the potentiality of diabetes, as much as in tuberculosis, was activated by an injudicious diet, too much fat, and too much carbohydrates. With a patient with evidences of tuberculosis and glycosuria and some symptoms of diabetes and not under skilled observation prior to that time they had no means of saying that the two conditions began simultaneously. They could not say they were associated and not dealing with an accidental infection. What was the relation between the two? He did not know. He did not find any statistical evidences that were of help. But there were certain facts gathered from the study of the family histories possibly indicating that there was some fundamental relation which was vaguely called constitutional, congenital, or hereditary conditions, and the conditions of metabolism of the patients. In the negro tuberculosis was common and diabetes was rare; among the whites they were relatively immune from tuberculosis and prone to diabetes. Diabetes mellitus and diabetes insipidus, transient glycosuria and a tendency to alimentary glycosuria were very common among these persons. Many of the patients that fell under his observation were obese or gouty. These associations were suggestive of some relationship between the two, and the diabetes was liable to eventuate into tuberculosis.

Dr. NELLIS B. FOSTER of Ann Arbor said he thought anyone could remember ten years ago when little or no work was done on this question in this country; today they could have a little pardonable pride in that they had so many ways, methods, and laboratories. The American temperament interfered with the work, and many small scientific facts were applied before they were linked with other facts. As an example of the good work done in many places was that of Dr. Fitz. The relationship between ketonuria and ketones in the blood due to functional change in the kidney at a time when, for some reason or another, coma was developing was an interesting theme. Because ketone was not excreted by the kidneys, it got into the tissues and set up disturbances. With regard to the pathology of the pancreas in diabetes, Dr. Allen had carefully stated the facts. It was notoriously a knotty question to determine those facts. He admitted that certain pancreases appeared close to the normal, while others showed gross changes. It was not fair, however, to compare the condition of the pancreas from diabetic patients with another pancreas from a patient who came to autopsy. The conditions which led to the death of a diabetic were peculiar. There were not only severe nutritional disturbances which gave rise to a peculiar blood picture, but there were other conditions which might cause certain organic changes. The work along these lines had been revised and their interpretation of the facts must be extremely guarded. They made a fundamental mistake in regarding diabetes as one thing, that was, as one disease. Glycosuria in a child did not mean diabetes in the sense they meant. The child would not get the characteristics of this disease unless the diet was bad and the child wasted. He thought he was the first to undertake to learn if keeping the child or young adult sugar free over long periods of time made any particular difference in the termination of that disease. Dr. Allen had stated that the pessimist should not treat this disease, but Dr. Foster thought the pessimist should not treat any disease.

Dr. D. D. VAN SLYKE of New York said that he had undertaken a monumental study of the acetone bodies in diabetes. One question arose with him, "Was acidosis caused by the acetone bodies, only the retained acid, or was it due also to the acidosis form of excretion?" The more acetone bodies in the blood, the more severe the acidosis. The acid formed in the body was neutralized by sodium carbonate. The acid doing the damage was retained, but it could be excreted and take alkali with it. This damaged the body by causing a double acidosis, the kind that developed the typical diabetic coma. These patients died because of the concentration of the acetone bodies in the blood and without Kussmaul's breathing. It was impossible to say whether death was due to an accumulation of the acetone bodies or not.

Dr. ABRAHAM JACOBI of New York asked permission to make one brief remark regarding the frequency of tuberculosis and the frequency of diabetes among the Hebrew race. He said he had looked over the literature carefully and he knew something about the Hebrews. For sixty years he had observed tuberculosis amongst

the Hebrews and amongst the poor. It had been repeatedly stated in the literature that diabetes was frequently found amongst the Hebrews; this was not true. It was more frequently found amongst the poor than amongst the rich. It was stated that tuberculosis was very rare amongst the Hebrews; such a false belief should be done away with.

Dr. Frederick Madison Allen of New York said that they had certain clews which led them to undertake the pathological studies of the human cases which gave them renewed hopes. He believed that the name "renal diabetes" should be changed to "renal glycosuria." A distinction should be made between the actual condition and the main symptoms. Any difference in the course and character could be explained by the thing back of it, such, for instance, as chronic pancreatitis in old persons. Diabetes was one thing, anatomically, a destruction of the islands of Langerhans. With that conception in view they could do more with the mass of glycosurias familiarly called diabetes. It was impossible to think of any diet being curative of diabetes. There was some specific cause interfering with the growth and development of the normal. It was a fact, too, that persons were killed because of the gloomy prognosis given them; one should tell the parent that the child would live for months and years. The treatment now was improving and the time would certainly come when these patients could be saved; the outlook was very hopeful.

Dr. E. P. Joslin of Boston said that 3 per cent. of his patients had tuberculosis with diabetes. With regard to the Hebrew race in Boston, a paper was published not long ago which covered a period of fifteen years, and this writer found that in proportion to the population there was a remarkable increase of this disease amongst the Hebrews compared with the other races in the State. It was best to keep patients on a low diet but yet maintain their weight. Dr. Joslin presented three groups of tables. In the first group ending March, 1916, the patients spent 33 days in the hospital, lost in weight 3.07 kilos, had an average diet of 26 carbohydrates and 54 proteins, and the last week showed calories per kilo .18. In the second group ending July, 1916, the patients spent 23 days in the hospital, lost in weight 2.87 kilos, had an average diet of 43 carbohydrates and 60 proteins, and the last week showed calories per kilo, .21. In the third group ending February, 1917, the patients spent 28 days in the hospital, lost in weight 1.6 kilos, had an average diet of 43 carbohydrates and 60 proteins, and the last week showed calories per kilo, .23. In his experience in the treatment of diabetes in children covering over 16 years, Dr. Joslin said he had never seen a case where the physician or the family had given up treatment but what the child was in a worse condition than he would have been if the treatment had been followed straight through to the end.

Dr. S. Solis Cohen of Philadelphia said that some 20 years ago he was called upon to deliver a lecture and he went freely over the work in his private practice, in the dispensaries and in the practice of others and he found that amongst the Jews diabetes was very common, both amongst the rich and poor. Whereas tuberculosis was rare amongst the rich Jews, though quite frequent amongst the poor and especially the Russians, but the proportion of cases of tuberculosis was less than amongst those of other races under the same social conditions.

Subacute and Chronic Non-Tuberculous Pulmonary Infections.—Dr. J. A. Miller of New York said that his report was based on 22 cases, but this report was not a report of the entire number of observations, there being twice as many or more. These cases he grouped into three types, the subacute, the subacute with recurrences and the chronic type. There were 9 cases in the first type with a clinical course similar to what was found in other types. This group was characterized by a mild onset, slight febrile disturbances lasting about five days. The expectoration consisted of a marked purulent discharge and sometimes with hemoptysis. There was no pain and the physical signs were characteristic and limited, as a rule, to the lower lobe. There was usually a slight impairment of resonance and a diminished vesicular breathing. There were moist ralês over the entire lobe. These cases usually presented the physical signs with tuberculous infiltration. He had seen evidences of consolidation. Among the nine cases the termination occurred in four weeks or six months. Sometime the physical signs persisted for two or three months and then entirely disappeared. The examination of the sputum had been thoroughly done for the tubercle bacilli and was consistently negative. One of the characteristic signs and the striking sign was the lack of evidence of pulmonary markings. There were 6 cases in the second type. This type was practically the same as the first type, but the condition recurred at intervals of several months or a year. In one instance there were four recurrences. In each recurrence the signs and symptoms were the same and always in the same area. The sputum was negative to tubercle bacilli. In 4 the *x*-ray was absolutely normal. In the third type there were 7 cases. The history of onset was as in the first type. The signs never cleared up. There were exacerbations in the symptoms. There was pain in three cases. In the sputum the pneumococci, Type IV, was found in 4 cases and the streptococci viridans in 3 cases. Unless taken in an acute exacerbation the number of bacteria was much less. The *x*-ray showed in all increased mottlings, very marked in 2. There were pleuritic adhesions in 4.

Summary: The ages ranged from 7 to 60 years. The subacute form predominated in young people. The seasonal incidence was the cold months. The site of lesion showed the left lobe affected in 13 cases, the right lobe in 5, both lobes in 3 and right upper and left in 1. Two patients had friction sounds. In 3 of the third type there was pain and thirst. Frank hemoptysis occurred in 2, and bloody sputum in 4 others. Cultures were taken in 21 cases and showed pneumococci, Type IV, in 10 cases; influenza bacilli in 8; streptococci viridans in 3 cases of the chronic type. The *x*-ray showed 7 normal cases; 1 with effusion; 10 increased mottlings; 4 pleuritic adhesions and in the chronic type.

Dr. James B. Herrick of Chicago said he had had six cases of the subacute type with recurrences. He had one case which recurred five times in as many years. The *x*-ray showed the same signs as in the subacute type. In the chronic type clearing up never seemed to occur. There were exacerbations of the symptoms that were similar to the acute type with the recurrences. He had had seven cases and three of the seven showed distinct pain. The *x*-ray showed something quite distinct. In all seven cases there were similar changes. In four there were evidences of pleuritic adhesions which were not present in the others. Recovery occurred in a few months in the subacute cases. In the Presbyterian Hospital in Chicago there were a great many of these cases.

Dr. Nathan E. Brill of New York said that there had been brought out a type of disease that had been familiar to him for years. Since the first pandemic of influenza in 1888 and 1889 this type had been known to him. In that pandemic he had seen such cases for the first time. In most of the cases the left lower lobe was attacked through the upper lobe, the right lobe, or both might be affected. During the last seven years he had frequently seen one or more such cases in the wards. He had demonstrated them to his students as cases of pulmonary invasion, non-tuberculous in character. Dr. Brill then showed slides.

Dr. Gerald Bertram Webb of Colorado Springs, Col., showed slides.

Dr. Hobert A. Hare of Philadelphia said that two or three years ago he read a paper before the College of Physicians and Surgeons and pointed out that there were no physical signs in these cases at all characteristic of tuberculosis. They made records of pulmonary lesions that occurred in the students and often advised them to lay off for one or two years. This showed how dangerous it was not to recognize that prolonged physical signs might exist in the lungs which were not due to any tuberculous lesion.

Dr. S. Solis Cohen of Philadelphia said that Dr. Da Costa had called atention to this class of cases that had been alluded to, especially the cases of recurrent bronchopneumonia following influenza. In 1880 he lectured on influenza and spoke of the persistent fevers, after influenza, stating that "like the poor they were always with us."

Dr. Lawrason Brown of Saranac Lake said that they should prove that these cases were not tuberculous before they were discharged. He asked regarding the condition of the antrum and the sinuses in these cases.

Dr. J. A. Miller of New York replied that his remarks were limited to the pulmonary symptoms alone. Aside from coryza there seemed to be no infection of the air passages.

A Roentgenologic Study of Pneumoconiosis.—Drs. H. R. M. Landis, H. K. Pancoast and T. G. Miller of Philadelphia presented this communication which was read by Dr. Landis. He said that 37 potters were sent for examination. Cement workers were also studied and it was well known that this dust produced definite changes in the lungs. Different dusts produced different kinds of damage and different individuals reacted differently with particular dusts. When one had to deal with organic dusts the changes were quite definite. Dusts had a tendency to collect at the junction of the lymph channels, and the terminal stage was a fibrosis which was quite extensive. Up to five years practically nothing was shown, but in the next ten years the linear markings became noticeable, and about the fifteenth year they had become quite distinct, and there occurred a diffuse fibrosis. There was also a marked dilatation of the bronchi.

Dr. George M. Kober of Washington, D. C., said that it had been estimated that more than one-half of the deaths from tuberculosis occurred among industrial workers who comprised about one-third of the total population. The majority of workers exposed to dusts of any kind had some kind of chronic disease of the respiratory tract and many of them developed pneumoconciosis. It might be concluded that the problem of preventive medicine was that of industrial hygiene. If they met the problem from this angle the hope of solving it might not be beyond realization.

Dr. W. M. L. Coplin of Philadelphia said he believed that a chronic lymphangitis was back of this trouble. Usually bronchitis, edema of the skin, and bronchial asthma accompanied this condition. The latent, mild chronic, or subacute, or even the acute type, showed the same process, a retardation of the lymph flow through the tissues.

Dr. Charles G. Stockton of Buffalo said that some years ago a similar case was described, and that since that time he had seen many similar cases in which the cause was the great amount of dust in elevators, where no precautions were taken to protect the elevator men and where no ventilation was provided. He now saw a great many of these cases such as Dr. Landis had described. The later cases went on to interstitial pneumonia, occasionally with cavity formation and sometimes asthma. They were described as "elevator pneumonia" of slow process.

Dr. David L. Edsall of St. Louis said that it had been shown that where there had been an exposure to dust, there was a proneness to chronic as well as acute pneumonia. An extraordinary thing about this exposure was the long period of time through which people could be exposed and apparently get no ill effects from it.

Dr. H. R. M. Landis of Philadelphia said that the fibrous form tended to retard the disease rather than accelerate it.

Cases of Aortic Aneurysm Treated by Wiring.—Dr. Hobart A. Hare of Philadelphia presented some slides and for the following reasons: First, they illustrated that much could be done to stop suffering; second, they possessed diagnostic interest; and third, they served to illustrate the safety of the method if its limitations were recognized and its technique was correct. As to the first, in 27 wirings he had always found the plan to allay or remove pain before the operation was completed. Often this pain required large amounts of morphine daily to make life tolerable. As the expansile pulsation was simultaneously decreased the relief of pain might be due to relief of eroding pressure or to the sedative effect of the galvanic current. In cases in which the aneurysm was the result of trauma the outlook was better than in those in which it was a manifestation of general arterial disease. As to the second, it was essential not to mistake a fusiform aneurysm, or a growth, for a sacculated or false aneurysm. These slides showed, too, the need of lateral as well as antero-posterior *x*-ray tests. As to the third point, the growth must be saccular for obvious reasons. The point of greatest bulging or giving way must be chosen. The needle must be properly insulated and not pushed too far so as to cause an electrolytic burn of the skin. The wire must be gold and platinum so as not to undergo electrolytic changes. Gold and copper alloy was eaten through rapidly. The wire must have spring but not be too strong. This was most important. If silver wire was used it would not coil. The positive pole must be in the sac as the use of the negative pole would liberate clots already formed. If street current was used it must be reduced, the operating table insulated, and the surgeon's feet covered with rubber shoes, or the patient would be shocked by grounding. The current must not be too strong. If it was it would cook or destroy the parts and cause death. One should start at five milliamperes and rarely go above forty, raising five every five minutes and then cutting down gradually. Never break the current. The wire should be 28 B and S gauge. This procedure if carried out properly as to technique was not dangerous.

Demonstration of Drop Heart; Its Variations in Health and Disease.—Dr. Chas. Lyman Greene of St. Paul, Minn., presented lantern slides. The almost constant association of drop heart with other structural defects was valuable in its identification when the characteristic outline was changed by disease. Its possibilities with respect to silent dilatations of high grade yet falling within the transverse dimensions were generally accepted as normal. Its special tendency was to minor decompensation.

(To be continued.)

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held May 28, 1917.

The President, Dr. J. Bentley Squier, in the Chair.

Committee on Amelioration of Hardships of the Families of Physicians Called Into National Service.—This was a Joint Committee of the New York Academy of Medicine and the Medical Society of the County of New York—chairman, Dr. Walter B. James; secretary, Dr. Edward L. Hunt; treasurer, Dr. J. Bentley Squier—formed for the purpose of collecting and administering funds for the support and care of wives and families of the medical men who might require financial aid as the result of the head of the family being called into the service of the country, which fund was started by Dr. Edwin B. Cragin with $10,000 and $5,000 by Dr. John F. Erdmann and $1,000 by Dr. Seth M. Millican.

Organization and Work of the Mayor's Committee for National Defense.—Mr. Willard Straight, chairman, told of the work that had been done by this committee.

Organization of Work of the Committee on Hospital and Medical Facilities of the Mayor's Committee for National Defense.—Dr. Sigmund S. Goldwater told of the preparations that were being made among the hospitals of the City to aid the United States Government. He said that a census of the public and private hospitals of the City disclosed the fact that they could place at the disposal of the Government at a moment's notice more than 4,000 beds. He told of a course that had been arranged to train volunteer nurses' assistants to care for soldiers and he urged the women to take advantage of this opportunity to serve the nation in an effective way.

Medical Schools in War.—Dr. Francis Carter Wood presented this communication. He told of the effort that was being made at Columbia University and other institutions to shorten the courses in the medical departments in order to provide as many physicians as possible for army and navy. It was necessary to change the plan of instruction materially to meet the conditions imposed by war. For example, students were given a thorough training in the treatment of gas poisoning which in peace times was not so necessary. He believed that the federal authorities should exempt from the draft young men who intended entering medical schools in the coming fall. It was highly impor-

tant to keep up the number of physicians, remembering that as the war continued the demand would be greater.

The Medical Corps, U. S. A.—Capt. A. N. Tasker, M. C., U. S. A. He spoke of the urgent need of 20,000 doctors to care for the wants of the first million men to go abroad. This was one of the most perplexing problems that confronted the army and navy and he urged the members of the Medical Society of the County of New York to do their share in solving it. The work of the physician in war time was illustrated by stereopticon views. He warned that there was a great task ahead of the profession in keeping up the health of the civil population who remained behind working at top speed in the raising of food and the manufacture of munitions and other supplies for the soldiers.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Oklahoma State Board of Medical Examiners.

Oklahoma City, January 9, 1917.

(*Concluded from Vol. XCI, p. 1126.*)

SURGERY.

1. Discuss the tonsil surgically: (*a*) Anatomy; (*b*) Infections; (*c*) Pathology; (*d*) Treatment, including operative technique.
2. Give description, etiology, and treatment of pterygium.
3. Give three dressings suitable for fracture of clavicle.
4. In fracture of middle of humerus what nerve may be injured? Give localization of symptoms leading to diagnosis of nerve injury.
5. Name two inflammatory diseases of the skin and give treatment.
6. Differentiate chancre and chancroid. Give treatment for chancroid.
7. In non-operative treatment of acute appendicitis give the salient points advocated by Ochsner, Murphy and Fowler.
8. How would you treat a severe lacerated, contused wound of hand not requiring amputation?
9. Discuss briefly the value of radiography in surgical diagnosis and treatment.
10. Give treatment for gunshot wound of chest; of abdomen.

TOXICOLOGY AND MEDICAL JURISPRUDENCE.

1. Give the differential diagnosis between strychnine poisoning and tetanic convulsions.
2. Name two drugs that, given in lethal doses, will produce convulsions, and give antidote.
3. Mention the antidote in the case of poisoning from silver nitrate. How does the antidote act?
4. Discuss briefly the symptoms of cocaine poisoning.
5. Name the antidote for alkaloids. How does it act?
6. Define Medical Jurisprudence.
7. Differentiate between burns inflicted during life and after death.
8. When is it legally permitted to produce abortion?
9. For what reasons may a physician refuse to give expert testimony?
10. Define expert testimony.

ANSWERS.

SURGERY.

1. The *tonsils* occupy the recesses between the pillars of the fauces, the anterior pillar being formed by the palato-glossus and the posterior by the palato-pharyngeus. On the outer side of each is the superior constrictor, and internally the buccal mucous membrane. Their arterial supply is large, from the ascending pharyngeal, ascending and descending palatine, tonsillitic and dorsalis linguæ arteries.—(From *Aids to Anatomy*).

Acute Tonsillitis probably arises from infection with micro-organisms, but cold is a predisposing cause. The inflammation may be superficial, and only portion of a general catarrhal inflammation of the velum and pharynx. Treatment is by a gargle of chlorate of potash.

Acute Follicular Tonsillitis is marked by general enlargement of the tonsils, with consequent obstruction to breathing and swallowing. Patches of exudation are seen at the mouths of the follicles, the temperature is raised, the bowels are confined, and the submaxillary glands are enlarged and tender.

Acute Parenchymatous Tonsillitis is inflammation of the tonsil, soft palate, and fauces, and often results in a peritonsillar abscess. The palate and anterior pillar are dusky and swollen, and the tonsil is pushed across to the mid-line. These conditions are distinguished from scarlet fever by the absence of the characteristic rash. Follicular tonsillitis is treated by giving calomel (5 grains), salicylate of soda, and an antiseptic throat spray. Peritonsillar abscesses must be opened by puncturing the most prominent part of the swelling and enlarging the opening with forceps.

Chronic Tonsillitis results in hypertrophy, and is usually associated with adenoids. The tonsils are large and pale, and show the large orifices of the crypts. Recurrent attacks of inflammation are common. The patients are usually mouth-breathers and snore at night. Deafness may occur from associated swelling of the orifice of the Eustachian tube. *Treatment.*—Fresh air and good food, together with painting the tonsils daily with glycerine of tannic acid, will cure some cases; but most resist this treatment, and so tonsillotomy is required. This may be done with cocaine or gas, and the tonsil is best removed with the spade guillotine. Forceps and a tonsil bistoury may also be used. Hemorrhage soon ceases in children. If it continues, iced lotion should be applied; if that fails, the galvanocautery. The tonsil may also be shelled out with the finger after snipping the mucous membrane in front of it.—(*Aids to Surgery*).

2. *Pterygium* is a triangular fold of membrane extending from the inner or outer part of the ocular conjunctiva to the cornea; the apex is immovably united to the cornea, the base spreads out and merges with the conjunctiva. It is thought by some to originate from pinguecula, the process extending to the cornea and drawing the conjunctiva after it. It occurs in elderly persons who are exposed to wind or dust.

Treatment: The pterygium may be dissected away with a sharp scalpel or Beer's knife, and cut off, the conjunctival defect being closed by uniting the upper and lower borders, undermining the conjunctiva if necessary to bring the edges together. The apex of the pterygium must be thoroughly excised from the cornea, and its attachment in this situation scraped or cauterized with the actual cautery, to prevent recurrence. Instead of cutting off the pterygium, it may be dissected up and stitched underneath the detached conjunctiva, either above or below; or it may be divided into two halves, of which one is transplanted above and the other below, being held in the conjunctival pocket by a stitch.—(May's *Diseases of the Eye.*)

3. *Three dressings suitable for fractured clavicle.* (1) *Velpeau's bandage:* "First place the arm in the Velpeau position, the hand of the injured side on the opposite shoulder. From the axilla of the sound side pass across the back, over the outer part of the injured shoulder, down across the middle of the arm, behind the elbow, across the chest, and through the axilla of the sound side to the point of starting. Next apply a horizontal turn on a level with the affected elbow. Repeat these turns until the elbow is covered with the vertical, and the wrist with the horizontal turns. The vertical turns should overlap two-thirds of each preceding turn, and the horizontal ones one-third. Secure the bandage by strips of adhesive plaster. (2) *Desault's bandage:* "Three bandages and a wedge-shaped pad are required. The pad is placed in the axilla of the injured side, base up. The arm is allowed to hang by the side, and the forearm is flexed at a right angle. The first bandage is used to hold the pad in place. Beginning at the base of the pad, descending spiral turns, encircling the chest, are applied down to its apex near the elbow, and then ascending spiral turns back to its base. To hold the pad up in the axilla, the first bandage may be terminated with a figure-of-8 turn of the opposite shoulder. The second bandage binds the arm to the side. Beginning at the axilla of the sound side, on a level with the base of the pad, descending

spiral turns are applied, with increasing firmness, down to the elbow, so as to carry the shoulder outwards. The third bandage is applied in the form of an anterior and a posterior triangle, the apex of each being formed by the axilla of the sound side, and the base by the humerus of the injured side. Begin the bandage at the axilla of the sound side posteriorly, pass over the affected shoulder, down in front of and parallel with the humerus, under the elbow, and across the back to the starting point. The anterior triangle is applied in the same way, by continuing the bandage through the axilla, across the chest, over the shoulder of the injured side, down behind the humerus, under the elbow, and back across the front of the chest to the starting point. (3) *Sayre's dressing:* "Two strips of adhesive plaster three or four inches wide, and long enough to extend around the chest one and a half times are prepared. Lint powdered with zinc stearate is placed in the fold of the elbow and between the arm and the chest. A collar of lint as wide as the adhesive strip is placed about the arm just below the axilla, and over this is applied the end of one of the strips of plaster, so as to form a loop; the strip is now used to pull the arm backwards, and is fastened around the chest. The hand of the affected side is placed on the opposite shoulder, and the second strip of plaster, with a hole for the point of the elbow, is run from the back of the sound shoulder, under the elbow of the affected side, over the sound shoulder, to the back, thus drawing the elbow forwards and upwards, and with the aid of the first strip, which acts as a fulcrum, forcing the shoulder backwards and outwards. A pad, held in place by a strip of adhesive plaster, may be placed just above the clavicle to press the fragment downwards."—(*Stewart's Surgery.*)

4. *In fracture of the middle of the humerus,* the *musculospiral nerve* may be injured. If this injury is sufficient to produce paralysis, the patient is unable to extend the wrist and fingers, or to supinate the forearm. Sensation, in the lower half of the outer and anterior aspect of the arm and in the middle of the back of the forearm, is lost or impaired.

5. The *treatment of carbuncle* is excision in those cases in which the carbuncle is favorable situated; the wound is allowed to granulate under antiseptic dressings. In other cases the honeycombed mass should be opened freely by crucial incisions, and as much of the necrotic tissue as possible removed by forceps and scissors. The wound should then be disinfected with peroxide of hydrogen and bichloride of mercury solution, 1 to 1,000, and dressed with warm antiseptic fomentations. The constitutional treatment is that of sepsis.

The *treatment of furuncle* is incision, when the boil is mature. Tonics, calx sulphurata, dilute sulphuric acid, brewer's yeast, and vaccines have been recommended in the treatment of this trouble.

6.

CHANCRE.	CHANCROID.
First lesion of a constitutional disease, viz., syphilis.	A local disease.
Due to syphilitic infection.	Due to contact with secretion from chancroid.
Generally a venereal infection.	Always a venereal infection.
May occur anywhere on the body.	Nearly always on genitals.
Period of incubation never so short as ten days.	Period of incubation always less than ten days (generally about three).
Generally single.	Generally multiple.
Not autoinoculable.	Autoinoculable.
Secretion slight.	Secretion profuse and purulent.
Slightly or not at all painful.	Generally painful.
As a rule only occurs once in any patient.	May reoccur in same patient.
Buboes are painless and seldom suppurate.	Buboes are painful and usually suppurate.

Chancroid of the penis may be treated by being sprayed with peroxide of hydrogen, dried with cotton, then touched with pure carbolic acid and then with pure nitric acid; afterwards a dressing soaked with black wash may be applied. The penis should be soaked in hot salt water (a teaspoonful of salt to a pint of hot water) every few hours; and the peroxide of hydrogen spray, the drying with cotton, and the application of the dressing should be repeated.

7. *In the non-operative treatment of acute appendicitis: Ochsner* recommends that hot moist compresses be applied to the abdomen; he advises hot boric acid solution and alcohol.

Murphy recommended enteroclysis by the drop method, to relieve the thirst.

Fowler recommended that the patient be put in the semi-sitting posture.

8. "*The treatment of a severe contused-lacerated wound,* in the absence of urgent hemorrhage, is directed to the shock. After this has subsided, the patient should be anesthetized in order thoroughly to disinfect the wound. Tissue whose vitality is questioned should be removed if it is unimportant, in other cases it should be retained unless known to be badly infected. All visible vessels, whether bleeding or not, are ligated, and provision made for abundant drainage. It is important to introduce as few sutures as possible, and to be sure that they do not unduly constrict the tissues, otherwise the subsequent swelling will cause necrosis. The wound is dressed with hot antiseptic fomentations. The later treatment depends upon the complications. If there are symptoms of sepsis, the whole wound should be opened, redisinfected, and packed with antiseptic gauze. Sloughing demands hot antiseptic fomentations, and removal of the slough at the earliest possible moment. Secondary hemorrhage may occur at this period from the separation of a slough involving the wall of an artery. The general health should, of course, receive proper attention."—(Stewart's *Surgery.*)

9. *Radiography* has been employed as an aid to *diagnosis* in the case of: Foreign bodies, fractures, dislocation, epiphyseal separation, injuries around a joint, diseases and tumors of bones, pathological conditions of the mastoid and accessory sinuses of the skull, tuberculous deposit or cavity formation in the lungs, thickened pleura, aneurysms, enlarged glands, tumors, various diseases of the esophagus, stomach and intestines, renal calculi, movable kidney, tuberculosis of the kidney, pus kidney, ureteral calculi, vesical calculi, and other conditions. Radiography is an aid in the *treatment* of disease, as follows: (1) It causes atrophy of the appendages of the skin; (2) it destroys organisms in living tissues; (3) it stimulates the metabolism of tissues; (4) it destroys certain pathological tissues; (5) it has an anodyne effect. It has been used in various skin diseases, malignant growths, ulcers, exophthalmic goitre and numerous other conditions.

10. *Gunshot wound of the chest.*—"The treatment, in the absence of serious hemorrhage or the lodgment of a foreign body, is disinfection and suture of the external wound and immobilization of the affected side of the chest. Hemorrhage from the internal mammary or intercostal artery may be controlled by ligation, or by pushing a gauze sac between the ribs and filling the inner end of the sac with gauze so that when drawn upon it will make pressure from within outwards. Excepting extensive wounds, bleeding from the lung is rarely fatal, as the bleeding is checked by collapse of the lung. In the absence of external hemorrhage, serious loss of blood is diagnosticated by the constitutional signs of acute anemia, and a rapidly accumulating hemothorax. Cases of this sort have been treated by the introduction of a drainage tube in order to admit air and favor collapse of the lung, but in the presence of serious symptoms one or more ribs should be resected, and the wounded lung dealt with directly by sutures or gauze packing. Foreign bodies should be removed if easily accessible, and the same rules as to the examination of the clothing, etc., apply here as elsewhere. If the foreign body is not easily found, it should be allowed to remain, unless it gives rise to subsequent trouble, when it may be definitely localized by the *x*-ray and its removal effected, if such be deemed advisable."

Perforating gunshot wound of the abdomen. "The treatment, even without symptoms of visceral injury, is immediate enlargement of the wound, in order to explore the abdomen, check hemorrhage, and close such visceral perforations as may be found. The abdomen is then flushed with salt solution, and closed or drained, according to the amount of soiling present. If the omentum protrudes it should be ligated and removed, while coils of intestine should be carefully washed with salt solution and returned to the cavity. In cases in which there is doubt as to whether or not a wound enters the peritoneal cavity, such wound should be enlarged and the diagnosis positively made, being prepared at the same time to treat any visceral injuries that may be found. In gunshot wounds on the battle field an exception has been made to the rule of immediate exploration, because it has been found that the chances of recovery are somewhat better without than with operation undertaken in the absence of proper facilities."—(Stewart's *Surgery.*)

TOXICOLOGY AND MEDICAL JURISPRUDENCE.

1. The *symptoms of strychnine poisoning* are as follows: "Strychnine produces a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."—(Witthaus' *Essentials of Chemistry.*)

In *tetanus*, the onset is gradual, is apt to begin with trismus, swallowing is difficult or impossible, the condition is persistent, consciousness is dulled or lost, and there is history of a wound or injury. In *strychnine poisoning* the onset is more sudden, the muscles of the jaw and neck are generally the last to be affected, there are marked remissions with muscular relaxation, consciousness is retained, and there is no history of a wound or injury.

2. *Two drugs that produce convulsions:* Strychnine and picrotoxin.

Antidote to strychnine: There is no chemical antidote; chloral or chloroform may control the convulsions.

Antidote to picrotoxin: There is no chemical antidote; chloral or chloroform may control the convulsions.

3. *The antidote to silver nitrate* is solution of sodium chloride; it acts by converting the silver nitrate into the insoluble silver chloride: $AgNO_3+NaCl=AgCl+NaNO_3$.

4. *Symptoms of cocaine poisoning:* "When a large dose has been taken the symptoms are not unlike those of atropine poisoning. There is dryness of the throat, tongue, and nose, difficulty of swallowing, faintness, and sometimes nausea and vomiting. The pulse is usually increased in fullness and frequency at first. The respiration also becomes more rapid, and there is much general nervous excitement, with general hyperesthesia. The eyes are bright and staring and the pupils dilated. The patient talks volubly and incoherently. Sometimes an erythematous eruption appears on the skin. The stage of depression soon comes on, when the breathing becomes shallow, the heart's action more rapid, and the face pale or cyanotic. The surface becomes anesthetic, and muscular twitchings and paralysis precede death, which is generally caused by paralysis of respiration."—(Riley's *Toxicology.*)

5. *The antidote for alkaloids* is tannic acid; it acts by forming a precipitate with the alkaloid which is practically insoluble.

6. *Medical jurisprudence* is the application of the knowledge of any of the branches of medicine to the problems and requirements of the law.

7. In *burns* produced *before death:* there is usually a blister, with a bright, red base, and containing a serous fluid, which is albuminous; occasionally, there will be no blister if there has been excessive shock; also, there will be a red line of demarcation between the injured and the uninjured parts, and this, being a vital process, is only developed during life.

In *burns* produced *after death* there is no true blister, no red base, and gas is present in place of serous fluid.

8. *Abortion is justifiable:* "(1) In pelvic deformity where there is sufficient space for a seven months' child to be delivered without injury. The object is twofold: (*a*) to save the child's life by obviating the necessity for craniotomy; (*b*) to spare the mother the dangers of craniotomy, cesarean section, symphyseotomy, or other operations that might be required if the pregnancy went to full term. (2) In cases where, in previous labors, the head of the child at full term has been prematurely ossified, or unusually large, so that labor has been difficult and dangerous, even though the pelvis were normal. The period of delivery need only be two or three weeks before 'term' in these cases. (3) In cases where the children of previous pregnancies have died *in utero* during the later weeks of gestation from disease (fatty, calcareous, or amyloid degeneration, etc.) of the placenta. (4) In conditions where the continuance of pregnancy seriously endangers the mother's life, such as: excessive vomiting; albuminuria; uremic convulsions, or paralysis; chorea; mania; organic disease of the heart, lungs, liver, blood-vessels, etc., threatening fatal disturbance of the respiration, circulation, and other vital functions; irreducible displacements of uterus; placenta prævia with hemorrhage; and in dangerous pressure upon neighboring organs from overdistention of uterus, due to dropsy of amnion, tumors, multiple pregnancy, etc."—(King's *Manual of Obstetrics.*)

9. In some states a physician is not allowed to disclose certain information without the consent of the patient concerned; such information is considered "privileged communication." In other states, such exemption is not allowed. The physician, however, must obey the ruling of the court.

10. In expert testimony the witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically,* this can only be done by those perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practise is accepted as an expert witness.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

A COMPEND OF HUMAN PHYSIOLOGY. Especially adapted for the use of Medical Students. By ALBERT P. BRUBAKER, A.M., M.D. Fourteenth edition, with 26 illustrations. 262 pages. Price, $1.25 net. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

PULMONARY TUBERCULOSIS. A Handbook for Students. By EDWARD O. OTIS, M.D. 220 pages. Illustrated. Price, $1.75. Published by W. M. Leonard, Boston, Mass. 1917.

REST, SUGGESTION AND OTHER THERAPEUTIC MEASURES IN NERVOUS AND MENTAL DISEASES. By FRANCIS X. DERCUM, A.M., M.D., Ph.D. Second Edition. 395 pages. Price, $1.25 net. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

CLINICAL BACTERIOLOGY AND HÆMATOLOGY FOR PRACTITIONERS. By W. D'ESTE EMERY, M.D., B.Sc., Lond. Fifth Edition. 310 pages. Illustrated. Price $2.75 net. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

SANITATION IN WAR. By MAJOR P. S. LELEAN, C.B., F.R.C.S., D.P.H., R.A.M.C. With 54 Illustrations. 336 pages. Price, $2.00 net. Second edition. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

DIAGNOSIS FROM OCULAR SYMPTOMS. By MATTHIAS LANCKTON FOSTER, M.D., F.A.C.S. 490 pages. Published by Rebman Co., New York City.

THE NATION'S HEALTH. The Stamping Out of Venereal Diseases. By SIR MALCOLM MORRIS, M.D., K.C.V.O. 152 pages. Price $1.25 net. Published by Funk & Wagnalls Co., New York City.

CANCER: ITS CAUSE AND TREATMENT. By L. DUNCAN BULKLEY, A.M., M.D. Price, $1.50. 271 pages. Published by Paul B. Hoeber, New York City

Therapeutic Hints.

Treatment of Diseased Nasal Sinuses and Ears.—William Ferguson gives some timely treatment for certain conditions of these organs to be employed by the general practitioner. For the removal of cerumen, if it is too hard to syringe out, drops of a solution of sodium bicarbonate, sixty grains to the ounce, may be placed in the ears for a few days, then the ear syringed. This is both economical and satisfactory. For acute inflammation of the middle ear when the drum has lost its lustre and is of a uniform, hyperemic shade in both the membrana vibrans and Schrapnell's, with the drum bulging, he advises a free incision in the drum with an upward and backward direction so as to establish free drainage. Syringe with a solution of saline or boracic acid every three hours, and as soon as the discharge has lessened use a solution of alcohol and boric acid. This solution may be used in the proportion of half and half, and dropped into the sick ear. In the early stages of the disease when the pain is severe, a dose of morphine may be given for relief. This is usually not necessary in children. Carbolic acid and glycerin one in twenty may be dropped in the canal for relief of pain also. *Do not use oils.* Dry heat is grateful.

For purulent middle ear infection and mastoiditis in the early stages rest in bed, light diet, initial dose of calomel followed by salines and free incision of the drum under gas are indicated, followed by a syringe of saline or boric acid solution every two hours; a blood count and an *x*-ray should be made. Ice bags or morphine are contraindicated as they mask the symptoms.

The indications for operation are: 1. The persistence of the acute symptoms in spite of the above treatment. 2. When the flow is so profuse that it could not possibly come from the middle ear alone. 3. When the symptoms show improvement but the blood count remains high and the *x*-ray indicates a mastoid cloudiness. 4. When the condition seems improved but the patient does not sleep but suffers from a dull headache. 5. When the temperature manifests a septic type. 6. When mastoid edema or subperiosteal perforation occurs. The temperature indications are not of much value; the blood count and *x*-ray findings are the best guides. Many cases under careful treatment clear up, but to be too conservative in the face of positive clinical and laboratory findings, is simply to invite disaster from sinus thrombosis or cerebral abscess.

For chronic purulent inflammation a solution of alcohol and boric acid may be used locally and at the same time syrup of the iodide of iron should be administered internally especially if adenoids are present, and a medicated spray for any nasal condition. Later, if possible, any abnormal condition in the nose or throat should be corrected either by operation or medical treatment. Prompt action is necessary in all cases of ear or nose conditions in order to prevent deafness in the patient.

Foreign bodies should always be syringed out; never use forceps. Insects may cause intense irritation; a few drops of ether in the canal will put an end to their activities until they can be syringed out. Perichondritis of the auricle needs a free incision through the auricle, clean out, and insert a through-and-through drain. Eczema of the auricle and canal should be treated with boric acid in alcohol, twenty grains to the ounce, and a solution of silver nitrate, 240 grains to the ounce, should be applied to the canal to destroy the skin infection, to be followed by yellow oxide of mercury placed on a cotton swab and swept around the sides of the canal.

Avoid any contact of water while washing, by inserting a small pledget of cotton in the canal. Furuncle of the external canal may be relieved by placing the thumb gently on the mastoid surface close to the auricle, being careful not to touch it, and press smoothly and firmly backward, thus preventing pain. Now glide the thumb forward against the auricle and pain is elicited. Incise deep down to the bone one or more times, as indicated by the extent of the swelling; clean out and pack with half-inch strips of gauze wet in saline or aluminum acetate solution. Cover with moist dressing, except in severe winter weather, and dress daily. Later, the solution of boric acid and alcohol may be employed.—*New York Medical Journal.*

Excessive Perspiration.—Whitla states that when there is no elevation of temperature associated with disease, the parts should be bathed in very hot water to which vinegar is added. Cold douching alone, or following hot sponging, often is useful, to be followed by smart friction. Unna advises that an ointment containing ichthyol and turpentine be rubbed in before bedtime. This should be washed off in the morning, after which a powder containing mustard is to be dusted over the skin affected. In cases where the skin is warm the use of ichthyol ointment or soap is advised. Of the powders to be dusted on the best is: starch 12 parts, tannoform 4 parts, boric acid 4 parts, and salicylic acid 1 part. This effectually deals with the miliary eruption or numerous sudamnia so often present. The internal treatment consists in a very dry diet with the least amount of fluids combined with 2 grains of sulphonal three times daily. Tincture of belladonna in 5-minim doses, or atropine in 1/200 to 1/100-grain doses three times a day, alone or with 15 to 30 minims of the liquid extract of ergot, may give relief.—*Dictionary of Treatment.*

Treatment for Hookworm Disease.—Oil of Chenopodium is found to be more efficacious than thymol in the treatment of this disease, as the final results are better. A saline is given first, followed the next day by 15 drops of oil of chenopodium at 7, 9, and 11 A. M.; at 1 P. M., a dose of castor oil containing 20 to 30 drops of chloroform is taken, and at 1.30 P. M. another dose of plain castor oil; at 2 P. M. the treatment is completed with a cup of hot tea.—*Indianapolis Medical Journal.*

Foot Treatment.—Hare recommends the following for swelling of the feet, also for tender feet, and in cases of excessive sweating of the same parts:

℞ Pulveris acidi salicylici,
gr. xx vel xl (1.3-2.60)
Pulveris acidi borici.....℥ij (8.0)
Pulveris amyli .....q.s. ʒj (30)

M. Sig.—Dust over the feet night and morning, after washing and thoroughly drying them.—*Practical Therapeutics.*

AN EARLY MEETING OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION.*

BY STEPHEN SMITH, M.D.,

NEW YORK.

THIS 73d annual meeting of the American Medico-Psychological Association forcibly reminds me of a similar event which occurred in the year 1852. I refer to the seventh annual meeting of the "Medical Superintendents of American Institutions for the Insane," which met on the 18th day of May of that year at the Irving House, at the corner of Broadway and Chambers Street.

Being a graduate in medicine of but one year and an entire stranger in the city I naturally had much leisure for other entertainment than attending my patients. I was attracted to the sessions by the novelty of seeing the practisers in this branch of medicine and listening to their discussion of the weird subject "insanity."

As the Association of Medical Superintendents of American Institutions for the Insane of 1852 was the American Medico-Psychological Association of to-day in its infancy, it may be pertinent to this occasion if, as a spectator of its seventh annual meeting, I give my impressions of the personnel of its members and the subjects discussed. The number of registered members in attendance was twenty-six and among the names we recognize the pioneers of American psychiatry. The absence of two founders was noticeable, viz., Dr. Samuel Bayard Woodward and Dr. Amariah Bringham, both of whom had recently died.

The president was Dr. Luther V. Bell of the MacLean Asylum, Somerville, Massachusetts, a tall, well proportioned man, of courtly manners and adapted to the position of presiding officer of such a dignified body. He took a deep interest in the papers presented and skillfully brought before the members the various subjects for discussion.

Among the more notable members was Dr. Isaac May, Butler Hospital, R. I.; Dr. Edward Jarvis, Dorchester, Mass.; Dr. John S. Butler of the Retreat for the Insane, Hartford, Conn.; Dr. C. H. Nichols, Bloomingdale Asylum, N. Y.; Dr. T. S. Kirkbride, Pennsylvania Hospital for the Insane, Philadelphia; Dr. H. A. Buttolph, State Lunatic Asylum, Trenton, N. J.; Dr. S. Hanbury Smith, Lunatic Asylum, Columbus, Ohio; Dr. Francis T. Stribling, Western Lunatic Asylum, Staunton, Va.; Dr. Thomas F. Green, State Lunatic Asylum, Georgia; Dr. C. Fremont, Canada.

The members of the Association impressed me as educated gentlemen of a higher type of professional character than I had been accustomed to meet. The president, Dr. Bell, and several others answered well to the description of the founder, Dr. Woodward, of whom it is said, "His personal appearance was commanding, and his carriage majestic. He was erect, and, though full in figure, his motions were quick and graceful. Although very civil and acceptable to all he seemed born to command. Dignity and ever-enduring cheerfulness sat upon his countenance."

The session continued five days and the subjects discussed related chiefly to the construction, equipment and management of institutions for the insane. The proceedings were published in an eight-page pamphlet. Dr. May read a paper on the following subject assigned to him by the President: "On the best methods of saving our hospitals for the insane from the odium and scandal to which such institutions are liable, and maintaining their place in the popular estimation; including the consideration of the question, how far is the community to be allowed access to such hospitals."

On motion of Dr. Kirkbride it was resolved: "That the standing committee on construction of hospitals for the insane be requested previous to the next meeting of the Association to prepare a series of resolutions or propositions, affirming the well ascertained opinions of this body in reference to the direction, organization and discipline of hospitals for the insane."

Dr. Stribling read a dissertation: "On the employment of male attendants in the female wards of lunatic hospitals."

Dr. Kirkbride read a paper: "On the comparative advantages of steam and hot water in heating hospitals for the insane, large and small, with an attempt to fix the ratio of radiating surface to the space to be warmed in the climate of the northern sections of the United States."

Dr. Jarvis made a partial report: "On the connection between insanity and crime."

The Association discussed: "The proper disposition of insane criminals in State prisons."

Such were the subjects which engaged the thoughts and deliberations of the founders of your Association two generations past. It was the period of the custodial care of the insane and the location of asylums, the construction of buildings, their equipment, the methods of commitment, the mechanical restraint of the insane, and similar subjects were living, vital questions. Insanity as a disease was based on the Pinel-Esquirol classifica-

*Address of welcome of the American Medico-Psychological Association to the City of New York, May 28, 1917.

tion, viz., its "symptomological expression." The brain as "the medium of sensation, will, and even thought, the highest of psychic functions," was a sealed book except to a few laboratory students. The somatic doctrine of the German schools, as the basis of interpretation of all psychic phenomena, had made slight progress in this country. It is highly creditable to the genius of Dr. Luther V. Bell, president of the Seventh Annual Meeting of this Association, that he combated with great force the French theory of Symptomatology and was sustained by van der Kolk of Holland, Morel of France and other authorities. From these facts we infer that at the period referred to, 1852, neither insanity nor phychology had a scientific basis and that the superintendents of institutions for the insane were devoted to the care rather than to the cure of the inmates.

It is a far call from 1852 to 1917. The child of seven is now the sage of seventy-three. We scarcely trace in the latter a lineament of the former. The membership of 26 in 1852 was 827 in 1916; its constituency was formerly limited to a few States, but now it includes the United States and also Canada, Cuba, and Porto Rico; its eight-page pamphlet of proceedings is now a volume of 400 to 600 pages, embracing every subject relating to insanity and the care of the insane. Even the name of the infant Association is but an item of record in history. The vast improvements in the care and treatment of the insane during the period 1852-1917 is a matter of common knowledge. That the initiative of these improvements and their practical application have been the fruitage of the intelligent and consecrated devotion of the members of this Association, impartial history will record in detail.

Members of the Association: I esteem it a great, indeed a remarkable privilege, that I am permitted to join in welcoming you to the hospitalities of New York City. It is a matter I think of record that the annual meetings of your Association in this city have given an impulse and an inspiration to its members, inciting to higher ideals and renewed consecration to the service of the insane. At no time in its history has New York furnished such facilities as now for education in the more abstruse medical sciences. Its seventy-five hospitals specialize every form of disease. Its medical colleges teach the principles and practise of the medical sciences and arts clinically, and its laboratories of research unfold the ultimate elements of health and sickness. These are all open to your visitation, inspection and inquiries. This is the sixth annual meeting of your Association in this city and I can assure you that the discussions in your meetings have a reciprocal effect in stimulating public inquiry and professional research in regard to the care and treatment of the insane in this city and State.

President Wagner: Far back in the eighteen-eighties, I recall your cheerful manners and happy and helpful remarks to patients as we passed from bed to bed in the Utica asylum. I congratulate you on the occasion of your exaltation to the highest honors of your profession. Your kind and sympathetic manners reminded me of Dr. Isaac Ray's description of the "Good Superintendent." "He never grudges the moments spent in quiet, familiar interview with them for thereby he gaineth many glimpses of their inner life that may help him in their treatment." Your success as superintendent and your elevation to the presidency of this Association has verified Dr. John P. Gray's remark, "Wagner will succeed in what he undertakes." I cannot resist the temptation of stating in this connection the pleasure it had given me to notice from time to time the progress in their profession of the young assistant physicians whose acquaintance I made in the hospitals for the insane in this State in the period 1882-1888. Macdonald, Blumer, Brush, Pilgrim, Wagner have attained to the presidency of this Association, the highest honor in the gift of the profession.

Looking backwards through the long vista of sixty-five years, I realize that the workers in the field of American Psychiatry, whom I knew in their active days, are now silent forever. In bringing to you, at this your Seventy-third Annual Meeting, a welcome from one who attended the Seventh Annual Meeting of your Association, I may repeat the words of Job's messengers, "I only am escaped alone to tell thee."

THE RESULTS OF THE PSYCHIC TREATMENT OF MENTAL TORTICOLLIS.*

(Fifth Paper.)

By L. PIERCE CLARK, M.D.,

NEW YORK.

It is generally admitted that true mental torticollis has rarely been cured or even greatly benefited. Treatment of the condition rests upon very unsatisfactory grounds (Oppenheim). Various reasons to account for this have been given. In the vast majority of instances the ultimate failure to respond to treatment has been attributed to the fact that torticollitics are recruited from that large class of psychoneurotics who, when seriously crippled by any severe mental or physical disorder, are incapable of ridding themselves of the condition because of the innate weakness such persons possess. Many writers have outlined the essential defects in the primary endowment of the torticollitic, thus showing the basic weakness of primary instincts, such as the judgment, the will, perception, and the like. They have loosely grouped these defects of character and personality under the heading of "mental infantilism" (Meige). In this latter term is embraced those character defects that make the possessor of them indecisive, vacillating, weak-willed, or an erratically brilliant, emotionally unstable person. Partly with the purpose of probing deeper into the essential makeup of such invalids, to ascertain the exact nucleus of these various character defects, especially upon the occurrence of mental torticollis, and yet with the still more practical purpose to find a better plan of treatment for the disorder than that which now exists, I have undertaken a careful and prolonged observation study of five cases of mental torticollis, the investigation covering a period of six years.

Inasmuch as the torticollis in all these individuals

*Read before the Neurological Section of Academy of Medicine, April 10, 1917.

was chronic, severe, and classic in type and all sorts of physical and drug therapy had been applied before such afflicted persons came under analysis, it was thought an intensive study and treatment of the disorder might be of both practical and scien-

Fig. 1.—Front view of Case I. before treatment, showing torticollis.

tific interest. In general terms one might say that all these invalids had a psychoneurotic constitution which was most comparable to that usually designated as psychasthenic in type. More or less unsciously these individuals seemed to have shrunk from their adult tasks in life and to have taken refuge in the substitution of a simpler and cruder type of reaction—that of their torticollis. All the patients spoke of the intense "nerve strain" they had endured before the torticollis developed, and the relief from the latter vague syndrome which their unfortunate disorder brought with it. They fully lamented their terminal state when they found how impossible was its riddance either by "force of will" or other simple device.*

Without further comment on the disease or its pitiable possessor, I shall cite briefly case notes of the clinical material under study:

*Notes of the first three cases will be only briefly summarized here. Anyone interested in their complete and detailed history, together with their analysis, may consult my initial reports in the Medical Record, Feb. 7 and 28, 1914.

Case I,* referred to me for study by Dr. Reginald H. Sayre six years ago, was that of a man 34 years of age suffering from a severe spasmodic torticollis. I have nothing further to add clinically to his case other than to say he has remained entirely free from his torticollis and has not been under treatment for any disorder for four years.

Case II came to me for treatment nearly four years ago and was that of a single woman, 29 years old, suffering from a persistent right spasmodic torticollis with an added spasm in the left trapezius and splenius. She has not been under treatment for two years, and has finally fully recovered from her torticollis.

Case III is that of an unmarried man of 30 who was

*In the discussion of this paper, Dr. Sayre said he thought the results that had been accomplished in this case were very gratifying, as nerve resection and physical gymnastics had not benefited this patient in the least. Dr. Sayre had recently been handling another case of an extreme character by administering very large doses of conium. For a time the symptoms had entirely disappeared. He was also given suggestive and morally supportive treatment in the hospital wards during this treatment, yet he had recently relapsed and was as bad as before. However, he didn't despair of improving his condition very considerably under a more conscious principle of correcting the pa-

Fig. 2.—Side view of Case I. before treatment.

tient's neurotic attitude than by psychoanalysis. It might be possible in time, however, that the latter would have to be resorted to if the patient's tendency to alcoholic indulgence should continue to be one of the mechanisms by which he tried to overcome his feelings of inferiority and inadequacy.

referred to me by Dr. Virgil P. Gibney.* Our patient is the oldest in a family of three. He was a blue baby for several hours. He remained weak and puny throughout childhood. At about 18 months he walked with a straddling, slovenly gait. "His knees were weak and he walked pigeon-toed." Various devices were tried

FIG. 3.—Condition of recovery from the torticollis as seen in Figs. 1 and 2. The dropping and atrophy of muscles of the right shoulder are due to the nerve resections.

to overcome the weakness of the legs. There was marked spasticity in both legs, which was more pronounced in the left. The spasticity, the contracture in the calf muscles, and the shambling gait were slowly overcome, and at the age of 16 he was fairly rid of the major portion of the whole spastic syndrome. He was backward in learning to talk, which was begun with difficulty at 15 months. His speech was scanning and syllabic, and this defect still persists in part. Some of the symptoms of the cerebellar diplegic syndrome (cerebellar diasthesia; Dana) are still shown in the speech, awkwardness, and failure to properly gauge the exact measurement of distance (dysmetria). The knee jerks are greatly exaggerated and a slight general spasticity is brought out in precise tests. The nature of the cerebellar injury in which the cerebrum probably also participated, shown in the slowness and irregularity of his mental development, was probably a slight grade of Batten's type.* In spite of being handicapped by this birth injury, the boy grew into a strong man whose endurance in long distance bicycle races is well known to the sporting world. He prepared and entered a medical school and did his student work up to the average of his class, until the second year laboratory work required much microscopic study. He then more or less abruptly developed a "professional" torticollis. The head was inclined to the left; the face was turned upward and to the right; the brow was wrinkled, and a few short clonic movements occurred at the end of complete rotation of the head. The muscles involved were the left platysma, the sternomastoid, the trapezius, and the deep rotators. The torticollitic movement was so characteristic of the purposeful one of looking through the microscope that from a casual relationship nothing seemed wanting between the cause and effect. The patient did not finish his examinations for the year, and left for rest and treatment in the country.

Analysis showed that this man, to begin with, had an organically defective nervous system. The very slowness and difficulty in physical coordination entailed in consequence a corresponding defect in mental action. Upon this physical and mental defect was added the intensive strain to attain to a level of lifework which was plainly unsuited to him,

FIG. 4.—Back view of Case I. showing recovery from the torticollis.

and he broke down in a "nervous prostration" with a mental torticollis as the chief symptom. Coupled with a psychasthenic makeup and marked feelings

*In commenting upon these cases Dr. Gibney states the general results are not only highly important from a diagnostic standpoint as to the real nature of the disorder, but the final results obtained were certainly very gratifying and worthy of being followed by all clinicians handling such cases. Heretofore he had not realized the very painstaking attention it was necessary to give to the minute details of the life of a torticollitic and the important role they played in recovering him from his disorder.

*F. E. Batten, "Congenital Cerebellar Ataxia," *Clin. Jour.*, Vol. XII, No. 6, London, May, 1903.

of inferiority, he was intensely infantile in his emotional attitudes. He had no love affairs whatever until late in adult life and claims never to have had anything to do with sexuality. Having always been slow in coordinated movements and thought, the

Fig. 5.—Case II. showing position of head at beginning of treatment three and a half years ago.

medical training required him to speed up; in order to accomplish this he took caffeine at night to keep awake. This situation steadily increased the nervous tension until the medical study was so fatiguing that a persistent, painful, "sticking" headache ensued. During the last few days at medical school he had frequent dreams which revived pleasant childhood experiences with the mother, and her pettings and caressings. He often stopped in the midst of hard study to indulge in daydreams of her, and pictured how pleased she would have been to know he was fulfilling her desires in taking up a medical career. As he became still more fatigued, and even felt "muscle beatings and tremblings" in various parts of the body, he would sink into his study chair and firmly close his eyes, striving to gain a respite from the aching fatigue by fancying his mother patted his head or shoulder. At such times he made the torticollic movements in time to the fancy of her rhythmic caressments. Soon after these orgies of pleasure the full movement appeared, and he could not repress it by the strongest exercise of the will. In a few weeks it advanced to its climax, as related in a previous description.

The case is similar to Case I. In both men the emotional life remained infantile; apparently there were no heterosexual longings, and no real love affairs. Athletics helped both to repress the little sexuality that had escaped parental prohibition. In this latter case the mother's plan for a medical training was followed after her death; but the task was too great, and the patient's unconscious desires seem to have escaped the adult task and regressed to its infantile longings and derived its satisfaction there at a cost of a mental torticollis. The effort to continue his studies having lost its pursuit at adult adaptation, the conscious effort to attain it was also lost, and failure in the medical career resulted. The physical disorder at birth only paved the way for the defect in adult adaptation.

This patient was given the usual minute explanation of his type of makeup and a rationalization for the presence of his torticollis. These talks at once improved the patient's mental state, and his torticollis was also less severe, but he did not improve beyond a certain point and he has not been even temporarily free from the full range of torticollitic spasm. Indeed, as the years go by there seems to be a more permanent fixation of the neck in its abnormal position. There are bone and muscle changes which are now more or less permanent. A full psychoanalysis was attempted, but the patient profited little by it except for an improved attitude toward his disorder. It would seem as though the underlying congenital palsy and its mental defect act as a bar to his further progress. Intensive mental analysis did what it could. The patient feels much more satisfied and hopeful for an ultimate recovery than any of his numerous physician friends actually possess.

Case IV is that of a young man of 28 who had his mental torticollis for only four months before he applied to me for treatment. He had had a short treatment of drug and physical therapy in the four months' interval. The torticollis was to the extreme right, involving the sternocleido, the trapezius, and the splenius, and finally involved the whole shoulder girdle and muscles, as shown in Figs. 7 and 8. One able neurologist who saw him at the beginning of his torticollis said: "His mental attitude is such as to defeat any rational attempts at cure, such as exercises, etc., as he is easily discouraged and goes from one physician to another, each change resulting in disappointment. He does not view the matter calmly and is too much excited over his condition. He is extremely self conscious about his disorder and this helps to increase it. There is a definite mental element. If he could only get over his extreme self consciousness I am sure this patient would improve. I would not recommend resorting to cutting the nerve that brings about the spasm, although in some cases this is of benefit."

The above fairly summarizes the intensive neurotic

Fig. 6.—Showing ordinary position of the head in Case II, which has been in evidence for the past six months.

attitude our patient took toward his disorder. As a boy he was fanciful and vague of purpose. He was not at all self reliant, and although clever in his occupation as a machinist and possessing a fairly good education, he was never able to cross New York City alone, and always had to be met and conducted about. He was

always "enormously" concerned about little aches and pains, and much frightened over them. He was slow to make friends. He was always rather peevish and boyish. His friends said he was petulant and chiding in manner and that he "had to be handled with gloves or he would crawl into his shell." He thought the

Fig. 7.—Front view, Case IV., showing torticollis at beginning of treatment. Note general body distortion produced by accessory spasm in other trunk muscles as a sequence to the torticollis.

world treated him rather poorly and that he never got what he deserved or worked for. He always thought he wasn't treated well at home by either parent. He was impatient and wanted to be general manager of the company before he had fairly started in the business. His mood was either "way up or way down, and one didn't know where to find him." The family said he put a "lot of wishing in things, then sat down on the job and expected it all to work out of itself."

This young man, naturally very neurotic and easily disturbed in his emotional life, was nevertheless a very

Fig. 8.—Back view, Case IV., at beginning of treatment.

good workman so long as he was occupied with actual concrete work, but when promoted to an executive position requiring him to generate his own activities, he first got depressed and confused, was not able "to see into the work nor its future," then began to feel nervous, had headaches, tension in the head, was insomnic, and had frightening dreams. During the latter part of his prodromal nervous symptoms his father died, and on his return to work things went even more badly than before. He became more irritable and grouchy, and felt a nameless dread. Then his head began to turn, and in the course of a few days he was in the position shown in the photographs.

After a talk giving a rationalization of his life had been undertaken, in which he was shown the neurotic features of many of his ways of handling things, he was given psychoanalysis for three months. In the first six weeks of analysis the patient made rapid progress. The spasm of the neck muscles gradually disappeared, while those of the back and shoulder, least contracted at the outset of treatment, disappeared entirely. The whole figure became erect, with but a slight yet more or less constant torticollis remaining. He slept better, and the dreams were less disturbing. He steadily gained in weight. From a state of extreme invalidism in which he did nothing but bemoan his fate, he became industrious, took up wood-carving, shoveled snow, sawed wood, and took long walks without an attendant. At this time he decided to release his fiancée from their engagement, on the ground of his present incapacity and the uncertain outlook as to their marriage. Soon after making this resolve, his

Fig. 9.—Showing normal position of head in Case IV., ten months later.

neck became stiffer and required the support of the hand to prevent the extreme retracting spasm of the trapezius and splenius. He began smoking to excess and withdrew within himself. He became cynical and indifferent to analysis. He finally persuaded himself he would not get well and that there was nothing more for him to live for.

At first the resistance in the analysis and his regression to a neurotic attitude toward life was thought to be due to his preparation to take up life in the country, a solitary existence far from encouraging friends and the physician. Analysis showed, however, the main fault was to a greater extent due to his having taken a more independent attitude toward his fiancée than he could yet maintain. Analysis of his feelings of inferiority and dependence resulted in his taking a less definite attitude relative to breaking off the engagement. Through all the latter part of the analysis the final great fault was shown to be the innate weakness of infantile fixation on the mother, and later, a conscious father-antagonism, but even more deeply, a too great dependence and attachment to the father, and this had arrested his main growth and self reliance. Just as the father's death had much to do with the exposure of his underlying infantile attitude coming to the fore in his ultimate nervous

breakdown, so the breaking of the engagement later precipitated him again into the old maelstrom of his original incapacity. In other words, he had lost the adult trend of interest in the girl as well as the job.

As to the torticollis: When he was working independently in the manager's office he found he could

Fig. 10.—Showing front view, Case V., at beginning of treatment.

do his work best when he turned his head away from the annoying manager who, in his peremptory manner of authority, was found to be the father-symbol. In earliest life the patient had used this gesture to turn away from painful situations when the father upbraided or accused him of ill conduct, when he turned toward the mother for comfort and support. The movement was the identical one of the torticollic spasm. Again, in a more adult setting he found his "legs wanted to turn away from going into the main shop," where he had to take charge of the men, but on bracing

Fig. 11.—Back view, Case V., at beginning of treatment.

himself against this tendency his head slightly turned in a torticollitic manner. Still again, when he was indecisive about his engagement and marriage, his head also "played him the same trick." A number of similar instances were also shown, and they were all traced back to the one great motive—that the torticollis was a turning away from a too painful situation and he regressed to an infantile type of habit which afforded him protection and comfort. It was not until all these affect reactions had been fully traced to their genetic source that the patient was finally released from his spasm, ten months from the beginning of treatment. Even then he had to outgrow this primary inadequacy and build anew a different and more healthful attitude toward life and his future purpose to become an independent factor in it.

Case V is that of a young man of 29 who had a right spasmodic torticollis of two months' duration when he applied for treatment. It had a gradual onset of two weeks before it was in the classic state shown in the photograph. He had taken all sorts of drug and physical therapy without effect. He had a mildly severe grade of neurotic constitution. He was tender-minded and sensitive and had trouble with his superiors; a feeling of inferiority and much tension was soon engendered and he finally had a nervous breakdown and a torticollis. After a short series of talks he submitted readily to psychoanalysis. In the ultimate analysis, as in all the other torticollities, the underlying inferiority was brought to the fore. After his mother became insane (paranoia) when the patient was twelve, he tried to transfer his intensive interest to the boy group, but this failed largely because of his too sensi-

Fig. 12.—Case V. after six months' treatment, showing complete recovery from his mental torticollis.

tive nature and because he had not been fully adapted to it by earlier continued association with them instead of with his parents. He then became rather shy, reticent, and shut in. At this time he went to live with his maiden aunt, who supplied many of the real mother attributes as well as others which were of a more intimate and personal nature. As he said, "Every elderly or married woman wanted to mother me." The attachment to the aunt made impossible any real satisfactory social settings with girls of his own age until he was twenty-seven years old. He then took the matter definitely into his own hands and became engaged, but underwent great "moral" torment and indecision. Coupled with this emotional conflict, a new stressful situation was induced in his inability to get on with the boss and the job (the authority symbol), and he soon contracted his torticollis and a "nervous breakdown."

As to the particular type of torticollic spasm: In all the stressful situations, with the boss, the father, at school, and even in "bracing for a scrap with the boys," he used to turn his head to the right—"a childish habit," he called it. When he fortified himself against this aversion of the head, he would avert his eyes instead. This gesture of turning eyes or head away from difficulties had existed from infancy. It had also been the initial head movement toward the mother when she petted and caressed him. Three months' analysis

almost completely restored this patient to the normal. This speedy recovery was partly due to the fact that his torticollis had been very recent when he came under treatment (three months); also, when the underlying defects of inferiority, infantile attachments and fixations were once psychoanalytically released, there was a more spontaneous readjustment of his attitude toward adult life and its purposes.

In spite of the fact that the patient is entirely free from his mental torticollis, many of the underlying inferiority defects in his personality are still in evidence. In a recent letter he writes: "I am more contented in my married life and feel assured that as time goes on I will improve. There are times when I am troubled mentally and have felt ready to give up hope, but I have observed a strong reaction and for this reason I believe the weakness will finally be overcome. The one great difficulty to be met, in one of my type, is lack of resolution, the one great asset necessary to success. The process of rebuilding goes on, and time will tell the tale. I am applying the principles laid down in our daily sessions."

As to the particular mechanism operative in these cases, Dr. James J. Putnam, who has followed types of cases like those described, has commented upon the principles as follows:

"According to the newer views, the disorder is recognized as mental in origin. This is now generally accepted, but the value of Dr. Clark's careful and long-continued studies is that they have brought out some of the actual mechanisms of the production of the disorder in a way that could not have been done prior to the discovery of the psychoanalytic method. I fully endorse Dr. Clark's view, that patients who suffer from this disorder are poorly adjusted for meeting the difficulties of life; or, to speak more accurately, their 'adjustability' is poor. The failure to make an adequate adjustment leads them to react in ways that are within their command, and that are accepted by them at first as fairly satisfactory. It seems out of place to characterize these simpler reactions as 'giving pleasure'; and yet it is hard to find any better designation. It is hard to say why one patient selects, as it were, torticollis for his reaction, and another some other coordinatory defect, or some wholly different symptom. It is, however, not improbable that the particular form of breaking down (reaction) is determined in part by some essential weakness of a physiological or anatomical sort. It is not improbable, for example, that there is a defect in coordination which makes it hard to keep the head exactly balanced—a defect analogous, one might say, to that met in some cases of strabismus. Then comes in the desire to 'turn away' or 'turn toward,' as symbolizing some part of the patient's repressed emotional desires and as recalling infantile associations. With some persons, a feeling of 'tension,' unattended at first by obvious movement, is present for a long time; and this muscular tension well represents the tension in such a patient's mind.

"It is not difficult to suggest a possible explanation to account for the violence of the spasm. It may be that the turning of the head clear around to one side represents a position which it is easier for the patient to maintain (actually and in a psychological sense) than an intermediate position. The raising of the shoulder, which is so common, is often a part of a secondary protective mechanism. I have a patient, a lady of middle life. She has been successful, up to a certain point, in a professional pursuit, and is decidedly capable and ambitious. On the other hand, ever since her childhood she has been obsessed with a desire for domination and for gratification of desires of a very primary and unacceptable character. Her childhood and adolescence were unsatisfactory, and marked by a positive craving for admiration and also by tendencies which set up feelings of humiliation to a very considerable extent. The torticollis itself came on after a number of years of relatively satisfactory immunity from all manifestations of trouble, but at a period of peculiar tension with reference to her private affairs. Special circumstances made the idea of *being looked at* abhorrent to her, while at the same time she could not endure *not being looked at*. The movement of the head to one side typified with absolute clearness the attempt on her part to escape from a state of tension which had become unendurable and also a desire to conceal certain local blemishes.

"The treatment has been conducted along lines of etiological analysis and temperamental education, and is, at last, resulting in much benefit. Besides prolonged and numerous interviews, educative gymnastics have been persistently employed, and attempts have been made to induce the patient to employ herself."

Therapeutic Remarks.—In criticism, it may be urged at the outset, as has been so frequently suggested before, that the underlying emotional inferiority of torticollitics cannot be removed and in consequence the torticollis will again return so soon as the strong therapeutic suggestion has worn off. I believe heretofore this termination has proven to be the case, simply because "suggestion and re-education" have been the methods employed, and not psychoanalysis. Nothing less than a sincere, complete reconstruction of the whole neurotic attitude can make these torticollitics remain well. If any torticollis is grafted upon an underlying mental defect such as may appear in psychopathic inferiors, within the strict meaning of that term, the condition cannot be permanently eradicated, for obvious reasons.* If the makeup is that of a simple neurotic constitution, though many of the instinctive trends of the primary intellect and emotion are weak, I believe the state may be completely corrected.

Again, in most cases psychoanalysis *alone* does not seem sufficient. The cases do not recover completely while under analysis (at least not in my experience). When simple mental analysis and psychoanalysis have been undertaken, the intensive transference—which seems so necessary for such cases to make in order to accomplish the analysis—will stand in the way of their getting quite well. Probably the deepest unconscious strivings are not freed under a moderate transference. I begin to make clear both the importance and the danger of this infantile filial-paternal transference after the first few weeks of psychoanalysis. As probably holds true in many other neurotics, the weaker the personality the greater the transference, and the longer it takes to recover such an individual from his torticollis and his underlying neurosis. In all these cases the unconscious strivings are those to be found in all neurotics. The pattern of the dreams is quite the ordinary.

There is a fairly definite mechanism for the torticollis; it is a gesture of the infantile personality, a turning away from the difficulties of adult adaptations under stress, and a use of a type of movement that has been employed more or less by that infantile makeup to gain protection and satisfaction which is not unlike the more intense shrinking and mental regression in other psychasthenics.

*If the young man in my fourth paper (MEDICAL RECORD, March 28, 1914) had had a true torticollis, I should have had grave doubts of his ever being able to recover from it as his whole psychic constitution was too inferior. The very fleeting and multiple character of his tic habits seem to have made him immune to so overwhelming a disablement as a genuine torticollis. It is interesting to note, however, that this young man has never recoursed to his tics after the initial treatment; he is by no means a productive citizen, but he fits into his world niche as satisfactorily as might be expected.

128 EAST SIXTY-FIRST STREET.

OSMOSIS, A FACTOR IN THE TREATMENT OF TUBERCULOSIS.

By P. SANFORD BAILEY, M.D.,

FORT BAYARD, N. M.

WHILE suggesting the following view, on the importance of considering osmosis in the treatment of pulmonary tuberculosis, I am well aware that we are dealing with many questions, not of immutable truth, but of expedience and practice.

Osmosis is, as yet, an imperfectly understood phenomenon, and it is not my desire to pretend to conclude a subject so grave; but rather, if you will, to induce questions which seem to be of considerable importance, and upon which a more general discussion may prove to be of no little value to us all.

Through the efforts of observers in all parts of the world and those who confine their attention wholly to research, our knowledge of tuberculosis is constantly undergoing radical changes.

We know, now, that the progress of this dreaded infection is arrested with a greater relative frequency than that of almost any other infectious disease. Paradoxical as such a statement may at first seem, it is nevertheless true, and in the light of our gradually accumulating knowledge, it is rapidly taking precedence over the older view that these cases were almost always hopeless.

Eminent pathologists, associated with the larger hospitals of Europe and America, where a considerable number of the indigent cases are submitted to autopsy, advise us that in the vast majority of these cases, where they have reached a fair maturity, the lungs either show quiescent foci; an active tuberculous process; or a calcified area as the remains of a previously active lesion which had healed. These indigent cases have, for the most part, succumbed to diseases other than tuberculosis.

These conditions are so constant through the large numbers examined annually, that these observers, who have ample opportunity to formulate statistics, have arrived at the conclusion that almost every living individual either has, or has had, or in all probability will have an active pulmonary tuberculosis. At least, this conclusion is justified through something more than 90 per cent. of the cases which come to autopsy. Briefly, this is the status of human susceptibility to pulmonary tuberculosis.

Hereditary transmission is unproved, though intrauterine infection is known. Hereditary predisposition is also quite uncertain. The disease being so widespread, so distributed in age and sex, its latent period so indeterminate, that reliable statistics are extremely difficult to collect, and much of the subject is still sub judice.

However this may be, it is true that the vast majority of people experience no noticeable inconvenience whatsoever during the brief interval that their tuberculosis may have been active. Indeed, there are many millions of individuals, living under every conceivable variety of climate and social environment, engaged in every possible occupational pursuit, who may truthfully say they have never known a single day of illness. And yet, many of these would reveal, upon careful examination, a greater or lesser tuberculous focus, with positive evidence of a permanent repair. With more or less difficulty a few might recall to memory, several days or weeks of slight malaise or indisposition, possibly accompanied by a slight dry cough. Others will perhaps remember having had several mild attacks of pleurisy, while others, again, will remember that they experienced for a month or two what was supposed to be an attack of la grippe, which was accompanied by a moderate degree of cough and fever. This is the vague, indefinite history, which these cases of spontaneous recovery present, in contrast with that of the occasional individual, who breaks down completely and has a long, distressing illness with which to contend.

Here, then, arises the perplexing problem of why the majority successfully resist an invasion of the tubercle bacillus, spontaneously, unconsciously, and without effort; while again, a comparatively small number experience considerable inconvenience, through a greater or lesser physical impairment extending over variable periods of time, before the activity is arrested. Why are some individuals so much more susceptible than mankind in general is known to be?

This question has baffled science in almost as great a measure as did the materia prima, or philosopher's stone of transmutation, the discovery of which became the universal problem of mediæval alchemists. But modern scientific research has perfectly and conclusively solved these perplexities of the early alchemist, and one by one the great problems of humanity are being solved through steadily advancing scientific knowledge.

In all civilized countries, notably in Japan, Germany, France, and America, scientists are assiduously working away at the complex problems of tuberculosis, and there is every good reason to feel great encouragement over the prospect of important discoveries in a future not altogether remote.

Considering the fact that bacteria were not discovered until 1700, when Leuwenhoek first demonstrated them, we have made a remarkable progress in the study of bacteria and infectious diseases. At first, bacteria were held to be animalculæ, and they were so considered until recent years, when researches of bacteriologists showed conclusively that they are minute and unicellular plants. In 1880, the remarkable discoveries of Pasteur in immunity induced by means of inoculating with cultures of bacilli attenuated in virulence, stimulated a world-wide interest in the newer science of bacteriology. Koch, in 1882, published his discovery of the *Bacillus tuberculosis*, and later gave us a valuable diagnostic agent in tuberculin. Many observers had noted the fact that normal blood serum is naturally bactericidal, and Metchnikoff (1900) showed that such action is largely due to phagocytosis, the enveloping and destruction of bacteria by the leucocytes. Wright, in 1903, discovered that this process is promoted by chemical substances (opsonins) in the blood, which act in some way upon the invading bacteria, preparing them for assimilation by the leucocytes before their toxins can affect the cells of the organism. Even within the year, Toga's notable paper on chemotaxsis and the possible advantages of cyanocuprol, a highly synthetical preparation, in the treatment of tuberculosis, illustrates an immense amount of advanced experimental work in the right direction.

But while we are patiently awaiting the discovery of a more desirable means of treatment we ought to have no hesitancy in considering the possible advantages of any measure already at hand in our efforts to improve, even a little, upon the usually accepted methods of the present. The latter may be briefly said to consist in prophylaxis and isolation, good nutritive diet, freedom from worry or anxiety, and an open-air life with as much sunshine as possible. To these I am disposed to add those measures which consistently promote osmotic activity.

In the direct morphology of the tubercle bacillus under normal conditions of development, there exists a decided disposition on the part of the bacillus to encapsulate itself in reparative structures of fibrous and calcareous nature, and to produce distinctively a localized process with well-defined reconstructive tendencies. The specific toxemia which follows is, as every one knows, not due to the tubercle bacillus itself, but to secondary organisms, principally the streptococcus, which readily engraft themselves upon the original tuberculous process and interfere very materially with the original efforts at repair. It is now quite generally conceded that without the streptococcus-pneumococcus group of Rosenow, tuberculosis would be a relatively mild disease.

Any treatment, then, to be efficient, should harmonize its therapeutics with this pathology; but at the same time, unless some specific attention is directed to the impaired subtle forces which influence osmosis, and many important physiological processes secondarily, the treatment would seem to be incomplete and unscientific.

Merely to say that an individual with pulmonary tuberculosis is run down, or has a lowered resistance, or an impaired nutrition, or to treat him accordingly, is as ambiguous and improper, in the light of our newer discoveries, as it is to use such meaningless expressions as blood-poison, female trouble, or catarrh, which convey no information whatsoever of any exact condition. It would seem to express something much nearer the truth when we say that the tuberculous individual has an impaired osmosis. In fact, the more I look into this subject the more convincing the evidence becomes that tuberculosis develops into a highly reactionary process, because of an interference with the normal osmotic phenomenon; in other words, because of a long-continued reduction in osmotic activity, which is one of the fundamental physical phenomena underlying the living organism, and upon which much of our metabolism depends, viz., growth, reproduction, assimilation, and repair.

In recent years the physical conceptions of the nature of the processes of osmosis have changed considerably. Although a brief description of the newer conceptions may not be out of place here, the very limited space that can be devoted to the subject forbids anything more than a condensed, elementary presentation. For fuller information reference must be made to special treatises.*

If upon the bottom of a vessel containing pure water we pour some water colored with a little aniline red, by delivering it through a funnel tube so as to prevent the mingling of the two, and then allow the vessel to remain at rest for a few hours, the color will be found to have diffused itself throughout the water so that a homogeneous mixture of the two is obtained. This is due to the continual movements of the molecules to and fro within the limits of the confining space. If the two liquids happen to be separated, as they frequently are in the body, by a membrane, this diffusion will still occur, provided the membrane is permeable to the liquid molecules, and in time the liquids on the two sides will be mixtures having a uniform composition. Not only water molecules, but the molecules of many substances in solution, such as common salt, may pass to and fro through membranes, so that two liquids separated from each other by an intervening membrane, and originally unlike in composition, may finally by the act of diffusion come to have the same composition. Diffusion of this kind through a membrane is frequently spoken of as osmosis.

The same phenomenon occurs between gases as well as liquids.

In the body, we deal with aqueous solutions of various substances that are separated from each other by living membranes, such as the walls of the blood capillaries or of the alimentary tract, and the laws of osmosis are of immediate importance in explaining the passage of many of the complex physiological fluids through those living septa, in sustaining the processes of assimilation, repair, and elimination of waste.

In aqueous solutions, such as we have in the body, we must take into account the movements of the solvent, water, as well as the substances dissolved. These latter may have different degrees of diffusibility as compared with one another or with the water molecules, and it frequently happens that a membrane which is permeable to water molecules is less permeable to the substances in solution.

The energy or force responsible for the diffusion of molecules in solution is an outcome of the intrinsic energy of the molecules which keep them in movement. This energy is designated as osmotic pressure. It can be measured accurately, although its exact nature is not understood.

When we imagine two masses of water separated by a permeable membrane we can readily understand that as many water molecules will pass through from one side as from the other; the two streams, in fact, will neutralize each other. If, now, on one side of the membrane we place a solution of some crystalloid substance, such as common salt, and on the other side pure water, here it will be found that an excess of water will pass from the water side to the side containing the solution. In the older terminology it was said that the salt attracted this water, but in the newer theories the same fact is expressed by saying that the salt in solution exerts a certain osmotic pressure. As a matter of experiment, it is found that the osmotic pressure varies with the amount of substance in solution. The stream of water to the side of the crystalloid will continue until the hydrostatic pressure on this side reaches a certain point, and the hydrostatic pressure thus caused may be taken as

*Consult Cohen, "Physical Chemistry for Physicians and Biologists"; H. C. Jones, "The Theory of Electrolytic Dissociation"; E. W. Reid, "Diffusion, Osmosis, and Filtration," in Schäfer's "Text-book of Physiology."

a measure of the osmotic pressure exerted by the substance in solution.

Two solutions having the same osmotic pressure are said to be isotonic. If one of the two liquids has a higher or lower osmotic pressure than the other it is said to be hyperisotonic or hypoisotonic respectively.

As a matter of fact, most of the membranes that we have to deal with in the body are only approximately permeable; that is, while they are readily permeable to water molecules, they are also permeable, although with more or less difficulty, to the substances in solution. In course of time, however, the substances in solution will have diffused through the membrane, and osmotic pressure on both sides will become equal.

The molecules of many substances, when brought into a state of solution, are believed to be dissociated into two or more parts known as ions. Substances which exhibit this property of dissociation into ions are known as electrolytes. The conception of electrolytes is very important for the reason that the act of dissociation increases the number of particles moving in the solution, and thereby increases the osmotic pressure.

The osmotic pressure exerted by crystalloids, such as the ordinary soluble salts, is, as we have seen, very considerable, but the ready diffusibility of most of these through membranes limits very materially their influence upon the flow of water in the body. Thus, if we should inject a solution of common salt directly into the blood-vessels the first effect would be the setting up of an osmotic stream from the tissues to the blood, and the production of a condition of hydremic plethora within the blood-vessels. The salt, however, would soon diffuse out into the tissues and extravascular lymph spaces and exert an osmotic pressure in the opposite direction. This fact, together with the further fact that an excess of salts in the body is soon removed by the excretory organs, gives to such substances a smaller influence in directing the water stream than would at first be supposed when the intensity of their osmotic action is considered.

In addition to the crystalloids, the liquids of our bodies contain a certain amount of protein, the blood, especially, containing over 6 per cent. of this substance. These proteins, which are supposed to be so important for the nutrition of the tissues, are practically indiffusible through animal membranes, so far as we know. This difficulty in regard to the indiffusibility of the proteins is met by the modern conception that the digested protein of the food circulates in the blood as amino-acids, and is supplied to the tissues in this form. The amino-acids have much simpler molecules, and may pass through the permeable membranes by diffusion.

It has been generally assumed that proteins in solution exert little or no osmotic pressure, but Starling and others have claimed, on the contrary, that they exert a distinct although small osmotic pressure.

In the body, then, water and substances in solution are continually passing through membranes; for example, in the production of lymph, in the absorption of digested foodstuffs from the alimentary canal, in the nutritive exchanges between the tissue elements and the blood or lymph, in the production of various secretions, and so on. In these cases it is a matter of greatest difficulty to give a satisfactory explanation of the forces controlling the flow to and fro of the water and dissolved substances, but there can be little doubt that in all of them the physical forces of filtration and osmosis take an important part.

Whenever, therefore, the normal osmotic activity throughout the body becomes impaired, all of the dependent physiological processes likewise experience a corresponding reduction below normal. Digestion, absorption, secretion, the elaborating functions of the blood or lymph, and many other vital functions, become impaired to a greater or lesser degree. After a variable period of time, which may be either months or years, the continued subnormal processes everywhere throughout the body slowly, though progressively, produce a condition of hypotonicity. The balance between repair and elimination fails to be maintained. The individual susceptibility to infectious bacteria increases; phagocytosis, which may be considered fundamentally a process in osmosis, becomes impaired; while the vital phenomenon, osmosis, also progressively declines. The increasing burden placed upon the already subnormal physiological systems becomes greater than they are capable of sustaining. The affected individual begins to realize that there is something radically wrong with himself, but pass over the whole realm of physiology though he may, it is impossible for him to definitely localize his pathology. He tires easily, and there is a general feeling of languor and lassitude. He observes that his digestion is not normal, and his physician, after discoursing at some length on "autointoxication," prescribes a modified form of diet. Again, perhaps, his attention is attracted to the torpidity of his liver, and a cholagogue is administered which temporarily arouses the hepatic function and carries the subject a few weeks longer over a delusive calm. Toxins, availing themselves of the inactivity of the bodily fluids, in which they find ready solution, continue to accumulate in geometrical proportions. The streptococcus, seizing upon the opportunities offered in diminished resistance and impaired phagocytosis, or other bactericidal agents, attacks the quiescent foci of the tubercle bacilli and arouses the latter into activity, though they may have reposed quietly in the lungs for many years. The delicate biological balances are overthrown and the period of latency is at an end. Sooner or later symptoms manifest themselves in the lungs, and upon a more thorough examination it is discovered that here is a case of incipient tuberculosis.

In view of the preceding facts, showing that the physical phenomenon of osmosis is very largely dependent upon a high degree of fluidity in the solvents of the body, it is certainly a logical deduction that any measure which promotes this fluidity should likewise promote osmotic activity. Also, it is a reasonable conclusion that this osmotic activity directly improves the functional characteristics of many physiological processes and tends to restore the balance between repair and elimination; improves the general tonicity of the body and assists very materially in combating infectious processes.

There are no measures as yet known which accomplish this with greater ease and facility than

plenty of good pure water, for water, as we have seen, is the important solvent in the body.

An important law of osmosis is that of Van't Hoff, which may be expressed as follows: *"At constant temperature, the osmotic pressure of dilute solutions is proportional to the concentration (the number of molecules or ions in solution) of the dissolved substance."* This is analogous to Boyle's law for gases.

But osmotic pressure alone is not the end to be attained. If there is insufficient water on one side of the permeable membrane to compensate the attraction on the other side, an inefficient physiological process is the result.

Excess of water in the body, like excess of crystalloids, it is true, is soon removed by the excretory organs. The amount of water absorbed is in accordance with the demand, not according to the supply. But this is also true of the very oxygen we breathe, and for which we appreciate the necessity of aërating the lungs with as much fresh air as we can get.

After all, respiration is merely one of the many vital phenomena in the body depending upon diffusion through membranes. In the lungs, where the medium of exchange through the permeable membrane is gaseous rather than liquid, the process is still governed by the same laws of diffusion. However this may be, it is nevertheless true that liquids, when taken in liberal quantities, will, in a measure, at least, remain in the system long enough to promote certain physiological activities. It is not an uncommon observation that the milk of nursing mothers is very materially increased in quantity when a liberal allowance of liquids is included in the diet. Surgeons who frequently operate to drain the gall bladder are quite familiar with the post-operative increase in the quantity of bile when a liberal liquid diet is prescribed.

Water constitutes something more than 75 per cent. of the bodily weight, and in the light of our present knowledge of osmosis it is certainly as necessary a requirement to place an abundance of water at the disposal of the body as it is to supply it with an abundance of fresh air.

It is a fallacy to suppose that the kidneys become overworked because of an abundance of pure water. This is as impossible in its conception as it is to regard an abundance of fresh air a detriment to the lungs. The truth is, the kidneys suffer a much greater degree of impairment through highly concentrated, acid urine, than would ever be possible through high degrees of dilution.

It is obviously impossible to accurately determine the exact degree to which liquefaction should be carried, or the quantity of water which may be regarded as adequate for each individual; yet, a very valuable index is the specific gravity of the urine, which should be brought to a point approximating 1.008, when the buoyancy at that point may be maintained through a regulation of the quantity of water ingested. The patient should supply himself with an individual urinometer.

Two hundred c.c. of water, which may be regarded as approximating the capacity of the ordinary drinking glass, taken every hour during the day, with an additional 200 c.c. at 9 A. M., 10 A. M., 3 P. M., and 4 P. M., is a good basic formula, but there should be no routine amount adjusted to all cases alike. This amount implies a normal functional activity of the kidneys and blood-elaborating organs. When these are severely impaired, or when the lungs show almost complete involvement, the prognosis will probably not be altered.

Mineral waters, or those containing a high percentage of soluble salts, should be avoided. Aërated distilled water is preferable. To avoid the undesirable possibility of a disturbed gastric function, warm water only is to be recommended. Iced water, or even cool water, is not only of little value, but may really be harmful. Communities depending upon neighboring streams for their supply should know that the water is absolutely pure, as shown by bona fide bacteriological reports at frequent intervals; otherwise, it is certainly unfit for any use. Organic matter is frequently removed from water by precipitation with alum, ferric chloride, or copper sulphate. When alum is added to a water it is decomposed with the formation of the hydroxide, which, as it settles, carries down with it all suspended matters and a large part of the dissolved organic matter and microorganisms. If an excess of an amount required to accomplish this is added, and free alum is consumed in the drinking water, it has a tendency to impair osmosis by dissociating the organic constituents of the bodily fluids from their aqueous solvent. Alum also renders animal membranes less permeable. For these same reasons, baking powder adulterated with alum is particularly harmful.

It is not to be presumed that efforts devoted to an improvement of osmosis only are to be considered. At best, tuberculosis is no easy foe to conquer, and certainly no element of the usually beneficial methods of treatment should be neglected. The osmotic theory is suggested merely as an adjunct, not as an ultimate end of treatment.

Medical literature abounds with so many excellent treatises on outdoor life, climate, rest, diet, etc., that any remarks in this connection relative to those subjects would be superfluous.

Suffice to say, that in no other disease is it so necessary to regulate the treatment systematically for such long periods of time, and to direct the attention persistently to the most minute detail. No measure in any treatment is of worth until it is carried out with every degree of fidelity. There are certainly no specifics for tuberculosis, and until such are discovered, patient application to the available measures at hand is our only watchword.

To facilitate brevity and clearness in this short paper I have endeavored to simplify the nomenclature as far as possible; avoiding a complication of the subject by omitting a description of the allied processes, filtration, selective absorption, selective diffusion, etc. Also, I have had some hesitancy in recommending measures which, being so commonly at hand, recognition of their value will not at once be appreciated. If, however, their adoption should improve our present statistics ever so little, I shall be rewarded.

The Sewer Rat and Weil's Disease.—Courmont and Durand state that even in regions hitherto exempt from Weil's disease the rats act as potential carriers of the malady.—*La Presse Médicale.*

MEDICAL ETHICS.

By F. H. BARNES, M.D.,

STAMFORD, CONN.

MEDICAL SUPERINTENDENT, DR. BARNES SANITARIUM.

UNDER section one, "Principles of Medical Ethics of the American Medical Association," we find the following: "A profession has for its prime object the service it can render humanity; reward or financial gain should be a subordinate consideration. The practice of medicine is a profession. In choosing this profession an individual assumes an obligation to conduct himself in accord with its ideals." What are the ideals of the physician? Are they not much the same as those of any learned profession? In other words, to be a man honored and loved in his community one must live clean and deal fairly with his fellow men. Add to this fair and square dealing with his brother practitioner and you have a pretty substantial code of ethics. It is not my purpose in this address to lay down a course for others to follow. I simply want to emphasize the necessity of our getting together on a more solid basis as a fraternity and this can only be accomplished by hearty cooperation and good-will. At the present time many threatening evils present themselves as a menace to our stability as a profession. The Judas is outside our gates and would willingly tear us asunder. The various cults are becoming stronger and this many times because one of our number is pleased to work in company with their propaganda. An instance of this came to my notice recently. A certain physician told me that one of his patients had troubled him with frequent visits relative to obscure symptoms of fancied disease. He made a careful physical examination and found all organs normal. He then told the patient his findings and said that he would be all right and not to worry about his condition. The patient persisted that he was ill and needed medical treatment. The physician told him he could do nothing for him, but that there was a doctor in the next block, a chiropractor, whom he had better see. And this at a time when our State Legislature is considering a bill for licensing these persons and giving them the title of "doctor." He would rather send his patient to one of them than ask the opinion of one of his fellow practitioners.

Petty jealousies will ingratiate themselves into every body of men, and what an evil it has become in our profession! We must rise above it and stamp it out. Physicians have high standing in their community because of their ability to combat disease and minister to the bodily welfare. They are placed on a high plane and have the respect and confidence of their patients and fellow citizens. If they are to maintain their standing they must do so by living up to the code of ethics set down by the great body of their number who have passed and gone. Never before in the history of medicine has there been so great a need for us to stand together. Natureopaths, Christian Science practitioners, and many other irregular sects are banding together to destroy the physician's standing before his clientèle. In a hearing before a committee at the last session of the Legislature I was surprised and chagrined to see two so-called reputable physicians working hand and glove with a group of this sort to combat a matter of honest medical legislation. Could these doctors of medicine suggest that they were following the code of ethics? "Do unto others as you would have others do to you," is a pretty good slogan, and if we carry it engraved on our banners we will be pretty safe in our ethical position. It is often said that no organization is stronger than its weakest member. Is it not a matter of ethics to hold out our hand to the weak brother and strive to make him a stronger, more potent factor in our midst? Do we have patience with the men in our profession who have not the same moral stamina as we have? Do we chide them in a fair-minded way for their shortcomings or do we hold aloof and point the finger of scorn?

This may sound like a sermon, but I assure you, gentlemen, it is not my purpose to have it so. I have been led to touch on this subject because I see the necessity more and more of our becoming stronger as we work for all that is good in the practice of medicine. Our duty to medical societies is a matter we often neglect. In chapter two, section two, of the principles already referred to, we find as follows: "In order that the dignity and honor of the medical profession may be upheld, its standards exalted, its sphere of usefulness extended, and the advancement of medical science promoted, a physician should associate himself with the medical societies and contribute his time, energy, and means in order that these societies may represent the ideals of the profession." A large number of physicians seldom attend a meeting of their county or State society, and even the local city or town society must hold out sufficient inducements to have a fair percentage of members present at its meetings. This should not be so, and we must wake up to our duty. We must stand together as one man or we will all go down before the onrush of pernicious legislation and selfish advancement of those who are seeking to cheapen us in the eyes of the public for their own financial gain. We hear so much of efficiency and preparedness, why not have a little in the practice of medicine? We should be willing to write a paper occasionally on some chapter from our own experience if nothing else. Many of our number say that they cannot do so, but if they will make the trial a few times it will soon be comparatively easy to write a good paper on some timely medical topic. If we cannot write papers we can certainly discuss them. Ofttimes I cuss internally upon hearing, "I have enjoyed the paper very much, but have nothing to add." One can at least ask a question now and then.

Under article six, section three, of the "Principles of Medical Ethics of the American Medical Association," relative to the secret division of fees, we read as follows: "It is detrimental to the public good and degrading to the profession, and therefore unprofessional to give or to receive a commission." This is only a part of the section. It seems rather strange that the medical superintendent of any sanatorium could give commissions to doctors for sending him patients under such a provision. If any deduction from the

weekly rate be made the patient should get the benefit of it and not the physician. All an established institution can do to fulfill its mission is to give those patients entrusted to it the best of medical treatment and care. Work for efficiency not for commissions if you wish to get results for all time. It would seem that the same rule might well apply in any division of fees between medical men. The slogan, "I am out to get the coin," is not one that adds to the dignity and high standard of medical practice. Every man has a right to attain high standing in his profession, and if in so doing he accumulates wealth honestly no one can criticise. In fact, we should all be proud of such a man, not jealous of him. I have already mentioned the ethical side as it refers to our fellows in medical practice, but want to refer to it again. How many of us go out of our way to call on a new arrival in his chosen field or strive to make the way easier for him? The world looks hard to the young doctor as he starts his life work, and how he warms up if he receives a little kindly notice! We have held aloof from each other all too much and the signs are apparent that we must get together and solidify our organization.

The meeting of the Connecticut Medical Society held at Bridgeport, 1916, was certainly a very pleasant one. Members generally have talked about it and how they enjoyed the social side. A special effort was made to make everybody warm up, with the result that many men became acquainted with each other who had never met before. To many men attending their first society meeting there is a feeling of diffidence. They are wondering just how they are to be received; in fact a new side of the medical world is opened up to them. Ofttimes their first impression is not a pleasant one, perhaps in part their own fault. If this occurs two or three times there is one less in attendance at future meetings. Recently I attended a meeting of a certain medical society in New York City. After the meeting I stopped a moment to talk with a member of the organization and he made the following remark: "This is a cold and clammy bunch." And he might be right in saying so. In defense of the president of that society I am glad to say he was right on his job and tried his best to make it pleasant for everybody. Gentlemen, if I read Medical Ethics aright, it is our duty to see that such things change. No matter to what heights we attain from an intellectual standpoint, in many ways we are no better than our most lowly brother. The doctrine of a handclasp and a smile help to make us stronger with our fellows. Let us try it out in this society.

Section three under article four needs no comment; it certainly is very plain in its meaning. It reads: "A physician should never take charge or prescribe for a patient who is under the care of another physician, except in an emergency, until after the other physician has relinquished the case or has been properly dismissed." Section four, article four, reads: "When a physician does succeed another physician in the charge of a case he should not make comments on or insinuations regarding the practice of the one who preceded him. Such comments or insinuations tend to lower the esteem of the patient for the medical profession and so react on the critic." We all know that in many instances physicians have made comments and insinuations which placed their fellow practitioner in no pleasant light with the family who perhaps they had treated for years. Better say nothing than to destroy the standing of one who has done as well as he knew in the treatment of his patient. A physician may treat all the members of a family successfully for years and then fall down hard in some particular case. Another doctor is often called, and if he happens to perfect a cure he is the hero of the moment. He must not forget, however, that sooner or later he may have the same condition confront him in his own practice. It is very hard for any physician to resist the plaudits of the family and friends if he makes an especially good cure or has a very successful operation. But the hurrah soon subsides and we are just as apt to get a good roasting on our first mistake in subsequent practice. The old saw is very true,

> "God and the doctor we alike adore
> On the brink of danger, not before.
> Danger is over, all is requited,
> God is forgotten, the doctor slighted."

We cannot afford to be sarcastic at the expense of our fellows; it is not square or Christianlike.

Another section of the code often overlooked is section nine of this same article. "When a physician is called to the patient of another physician during the enforced absence of that physician, the patient should be relinquished on the return of the latter." Simply a case of fair dealing, and such a course should always be followed. A part of section two, chapter three, relative to epidemics, should be noted. "At all times it is the duty of the physician to notify the properly constituted health authorities of every case of communicable disease under his care, in accordance with the rules and regulations of the health authorities of the locality in which the patient is." It is the duty of every physician to cooperate with the Board of Health in his town or city and such boards of health should not be the tool of politicians. Men who establish health laws and regulations should be the most intelligent and capable of our fraternity. They should rise above petty jealousies and bickering, standing together for all that is best and most scientific in progressive medicine. Remembering that the eyes of the public are upon them and that they are expected to stand in the gap in the face of dreaded disease. Is it not our duty to stand for more central regulations of health matters state-wide in character?

I have simply tried to suggest in this brief paper the necessity of a better understanding of our Code of Ethics. Let us rise up and acquit ourselves as men in this matter. We must stand together shoulder to shoulder in our fight against those who would discredit us. This can only be accomplished by a knowledge that we stand for high principles of ethics in our practice and in our relation to our associates. Truest altruism has always been associated with our profession in the past and may it ever be one of high morale. We must deal with our clientèle kindly and walk among them in a manner which will always command their respect and support. Ours was ever

called a noble profession. Let us follow out our code of ethics that we may always be worthy of the high standing to which we have attained.

A MIXED TYPE OF NEPHRITIS.

REPORT OF A CASE WITH AUTOPSY FINDINGS.

By HENRY MONROE MOSES, B.S., M.A., M.D.,

BROOKLYN, N. Y.

ACTING ATTENDING PHYSICIAN TO THE KINGS COUNTY HOSPITAL; ASSISTANT ATTENDING PHYSICIAN TO THE NORWEGIAN HOSPITAL AND HOSPITAL OF THE HOLY FAMILY.

I REPORT this case because of several interesting features connected with it: (1) The ability to follow the patient from his first admission into a hospital for the nephritis to his death; (2) the rapidity of accumulation of fluid in the tissues and in the several cavities; (3) the change in the disposition and temper of the patient; (4) the apparent susceptibility to infections, which eventually caused the death of the patient; (5) the duration of the condition after requiring hospital attention—less than eleven months; (6) the findings at autopsy.

The patient, a man, thirty-four years of age, had been a truck driver since he was fourteen years old. He entered the hospital for the first time in this illness on March 17, complaining of puffiness of the eyelids, general swelling of the body and genitalia, pain in the lumbar region, and shortness of breath. There was no family history of cancer, syphilis, insanity, heart or kidney disease. The patient remembered having had measles when a child, and pneumonia with pleurisy when twenty-six years of age. He denies having had scarlet fever, diphtheria, rheumatism, malaria, lues, or Neisserian infection. Associated with his occupation as truck driver, we find him to be a heavy drinker—he drinks all the whiskey and beer he can get—using also considerable tobacco. He has been married eight years; his wife has had two children and no miscarriages.

The following history of the present trouble as obtained from the patient is that he felt perfectly well up to three weeks before admission to the hospital, at which time he caught a severe cold after exposure to rain when unable to change his wet clothing. He states "he felt stiff all over the next morning and was all choked up." He had severe pain also in the lumbar region. He tried self-medication, became worse, had to stop working, went to bed and was brought to the hospital for treatment. His condition on admission was as follows: A large-framed, well-built, muscular young man, with a skin doughy, edematous, rather clammy to the touch, and very pale. The eyes seem rather small, due to the puffiness of the tissues. The sclera is clear, there is no jaundice present. The mucosa is pale and anemic-looking; the teeth, fair; the tongue, slightly coated, and the breath offensive. The tonsils are clear. The neck is edematous, no enlarged glands are present, and the pulsation of the carotids slight. The chest tissues are quite edematous, the pitting on pressure remaining for some time. Expansion is good and equal on both sides, resonance slightly impaired by the edematous chest wall. The respiration is deep and moderately slow. The cardiac borders, the right border is one inch to the right of the right parasternal border; the left, just inside of the midclavicular line. The apex beat is in the fifth interspace. The sounds are clear, regular, distinct but not strong. There is the suggestion of a soft, blowing murmur at the finish of the first sound heard over the entire precordium. The abdomen is slightly protruberant, muscular, firm and resistant. The walls are thick and markedly edematous. Flatness is present in the extreme flanks. There is no fluid wave and no tenderness. The liver is normal in consistency and two and one-half inches below the costal margin. The spleen is not palpable. The extremities are much swollen, the pitting on pressure remaining for some time after the pressure has been removed. The glandular system shows no enlargement.

The patient at the time of this first examination felt extremely weak especially in the legs. He had had no vertigo nor dizziness, and no spots before his eyes. His blood pressure was 150 mm. systolic, 135 mm. diastolic. The blood examination showed 4,480,000 red blood cells, 11,500 white blood cells, with 86 per cent. polys, 14 per cent. small lymphocytes. Hemoglobin, 65 per cent. The urine was acid, varied in specific gravity between 1008 and 1015, contained large quantities of albumin, no sugar, many epithelial, granular and hyaline casts with many red and white blood cells. The blood Wassermann was positive. Examination of the eyegrounds by Dr. H. M. Smith showed marked edema of the retina with a few hemorrahges.

Sixteen days after admission, the patient had a severe chill and developed a diphtheria with a temperature of 105°. He was given antitoxin and recovered from this condition. Upon the improvement of his symptoms, the patient insisted upon his release from the hospital and left April 17, after a stay of one month. Paracentesis was not performed during this stay; there was present most of this time a marked edema of the face, body, and legs. He had severe headaches at times, and was irrational immediately after the development of the diphtheria.

We had no trace of the patient from April 17 until June 23 when he again came under hospital care with a general edema and fluid in the abdominal cavity. On June 25, paracentesis abdominalis was performed and 3960 c.c. (132 oz.) of fluid withdrawn. On July 1, paracentesis abdominalis was again performed and 8460 c.c. (282 oz.) of fluid withdrawn. On July 22, 8400 c.c. (280 oz.) of fluid were removed. On August 1, the patient was very edematous with the fluid reaccumulating rapidly in the abdomen. On August 6, 5400 c.c. (180 oz.) of fluid were removed and on August 15, 3060 c.c. (102 oz.) were removed. The patient had been in the hospital from June 23 until August 16, when he demanded his release. He claimed to feel better, although there was no improvement in his condition. His urine during this stay at the hospital was scanty in amount, of a specific gravity between 1.013 and 1.017, contained large amounts of albumin, many granular and hyaline casts, and red and white blood cells.

On August 28, he reappeared at the hospital with edema marked throughout the tissues and fluid in the cavities. Paracentesis abdominalis was performed on August 29, and 3700 c.c. (123 oz.) of fluid withdrawn. The urine was similar in character to that on the previous visit. The patient left the hospital on the following day, August 30, to reappear in about two weeks. On September 17, he returned in a condition similar to that on his former admissions, but with more fluid in his tissues and less in the cavities. He remained one week, until September 25, but was not tapped during this visit. On October 7, he again returned with the symptoms aggravated and was treated for eight days. The urine was of low specific gravity, 1.014, still loaded with albumin, hyaline and granular casts, red and white blood cells, and renal epithelium. Paracentesis was performed on October 13, the amount of fluid withdrawn being 7350 c.c. (245 oz.). On October 15 he was discharged, feeling better, but unimproved.

On November 5, we find the patient again appearing for hospital care. Dyspnea and edema are the chief complaints. Nocturia is beginning to be troublesome, the patient being compelled to void four or five times nightly. There are no evidences of a pleuritic friction rub at the present time. The abdomen at the umbilicus measures forty-one inches. An examination of the eyes at this time shows the pupils equal, reacting slowly to light and poorly to accommodation. There is marked edema of the retina with a few hemorrhages. There is no arteriosclerosis of the vessels, and no albuminuric retinitis. On November 6, 9600 c.c. (320 oz.) of fluid were withdrawn from the abdomen, the measurement changing from forty-one to thirty-seven inches. Paracentesis was again necessary on November 13, when 9840 c.c. (328 oz.) of fluid were withdrawn. The ascitic fluid at this time was grayish white, opalescent, of specific gravity 1.012, alkaline in reaction, no cells except a few endothelial ones. The urine was scanty, with a specific gravity of 1.013 to 1.016, heavy albumin, many granular, hyaline and degenerated casts. The systolic pressure was 165 mm. The patient left the hospital November 19, contrary to advice.

On December 15, he returned with general anasarca, dyspnea, headaches, nausea and vomiting, the symptoms of previous attacks were much aggravated. Paracentesis was performed on December 17, and 6900 c.c. (230 oz.) of fluid withdrawn. At this time the patient remained in the hospital two weeks, leaving December 29 at his own request with his symptoms relieved. Although he looked anemic and pasty the blood showed hemoglobin of 70 per cent. and a red cell count of 4,420,000. The quantity of urine was small, the specific gravity 1.016 to 1.018, a large amount of albumin, with hyaline, granular casts and white blood cells.

Again, on January 26, the patient entered the hospital complaining of dyspnea, general edema, and weakness. Paracentesis was performed the same day and 900 c.c. (30 oz.) of fluid withdrawn. On February 6, 5760 c.c. (192 oz.) of fluid were withdrawn from the abdomen. There were signs of fluid in both pleural cavities, but it was not considered necessary to aspirate. On February 7, the patient, who was usually irritable and complaining seemed much more disagreeable. There was a slight droop of the left eyelid, and the face seemed slightly drawn to the right. His hearing became less acute, and he complained of pain in the left ear. Pus was obtained from the left ear February 8, and from the right ear on the ninth. The patient became more and more irritable, grunted and groaned considerably, and gradually became comatose. The pupils were contracted, the left more than the right, the neck muscles stiffened, and the hand was placed to the head and neck as though in pain. The patient was absolutely deaf and could not be aroused, although there was resistance to passive motion of the arms and legs. The reflexes were increased and Kernig's sign was present. Paracentesis was again necessary and on February 12, 3450 c.c. (115 oz.) of fluid withdrawn. Physical examination of the chest on February 14 showed a leathery rub on the left side from the third rib down. This sound overlapped the precordium and obscured the heart sounds. The right chest had no friction rub, but signs of fluid were present. The abdomen was distended, tense, and held rigidly. There was dulness on the dependent side.

The patient died on the following day and the clinical diagnosis made before autopsy was chronic parenchymatous nephritis, cirrhosis of the liver, dry pleurisy in the left chest, hypertrophied heart, acute mastoiditis, and uremic meningismus.

We were fortunate in this case to obtain permission for a complete autopsy, which was performed by Dr. B. T. Terry, director of the pathological laboratories at the Kings County Hospital, to whom I am indebted for the report of the findings. A summary of which is as follows:

There is edema of the pia arachnoid, with congestion of the vessels on the left side of the cerebrum. Pus is present in the inner ear on the left side. On the right side, we find pus external to the drum. Microscopic examination of this pus shows steptococci and traphylococci. Fluid is present in both pleural cavities, in the pericardial sac, and in the abdominal cavity. Fibrinous peritonitis and pericarditis are present. There is an obliterative pleurisy on the left side. On the right side there are a few chronic pleuritic adhesions. The heart is enlarged, with atheroma of the aortic valve and atheroma in the aorta behind the valves. There is marked atheroma of the coronary arteries. The myocardium shows cloudy swelling. The lungs are enlarged and the pleura thickened. Acute bronchitis is present. There is edema and congestion of both lungs with atelectasis of the lower right lobe. Perisplenitis and interstitial splenitis are present. The kidneys show a chronic diffuse nephritis on macroscopic examination, the parenchymatous changes being most marked. There is also marked atheroma of the aorta. Microscopic examination of sections of the kidney show marked increase in the interstitial tissue and changes in the glomeruli and tubules, where in places all the epithelial cells are destroyed, or in the process of destruction. The liver shows the changes found in chronic alcoholism.

We have been able to follow in this patient his history and course of the disease from his first admission to a hospital for his kidney condition until his death, occurring two days less than eleven months. He was, during this period, a patient at eight different times in hospitals, twice at Long Island College Hospital and six times at the Kings County Hospital, where he died and where the autopsy was performed.

This is a case commonly diagnosed as chronic parenchymatous nephritis, but which on more careful study and autopsy we find to be a mixed type, a nephrosis and a nephritis. We have much fluid in the tissues and the cavities, a low specific gravity of the urine, large quantities of albumin, all kinds of casts, hyaline, granular, degenerated, a moderate systolic blood pressure, retinal edema, and hemorrhages, but no albuminuric retinitis, and a terminal infection with autopsy findings of changes in the glomeruli with degeneration and disquamation of the tubules with considerable increase in the connective tissue of the kidneys, and the liver showing the fatty changes most commonly found in chronic alcoholism.

The more recent tests for renal function—the test meals, the salt and water excretion, the blood examinations of urea, uric acid, creatinin retention were not performed upon this patient, as these examinations were not being made at the Kings County Hospital at the time of this patient's admissions. At present there is under observation at the County Hospital a case very similar in history and course to the one reported above, upon whom these tests are being performed. If an autopsy is obtained a comparison of the two cases may be reported at a later date.

CLUB FOOT AS A PRODUCT OF EVOLUTION.

By TRUMAN ABBE, M.D.,

WASHINGTON, D. C.

If we study the course of an acquired club foot in a child and see the changes that have followed the destruction of cells in the lower part of the spinal cord after infantile paralysis, we note first the loss of power in the muscles and later the deformity of the limb due to the modification in the bones from lack of use of the muscles and, in course, of time from the non-development of the bones. In the acquired cases we know that the primary lesion is loss of nerve control of these tissues that in the end show non-development.

In the congenital cases of talipes we find varying degrees of the typical equinovarus similar to the different stages of the acquired talipes. The prenatal course of development is not easy to follow but is therefore all the more worthy of our study. The most common type of congenital talipes (equinovarus) at the time of birth shows a condition similar to the advanced stages of the acquired talipes. The bones are abnormal in shape and the muscles are small and weak, especially in one group. The nerves so far as we know have been but little studied. In connection with the nerves we think of the conditions frequently associated with the congenital club foot of spina bifida, hydrocephalus, paraplegia, bladder and rectal loss of control, which are all lesions in the central nervous

system. It is not unusual to find associated also extra toes, webbed toes, absent toes, clubbing of both feet, and less often similar deformities in the hands. One notices with interest the frequent symmetry either complete or partial of these deformities and symmetry always suggests a lesion in the central nervous system. Congenital absence of limbs sometimes described as intrauterine amputation is not infrequently associated with the clubbed foot and we believe due to the same general factor. (See *Am. J. Obstet.*, 73, 6, 1916, Case of Congenital Amputations.)

The extra toes and absent toes are very interesting in the light of comparative anatomy. We may compare the arm and leg of the same individual or the marked changes that have taken place in evolution of the race. If we compare the two limbs of man and note the nearly equal size and nearly equal importance of function of the radius and the ulna and the equality in size of the digits beyond them and then note the large tibia and the great toe and the comparatively slender fibula and diminutive little toe with the less significant function of the post axial group, it surely is suggested that a club hand would be a much greater variation from the normal hand than a club foot would vary from the normal foot. And we all know that the club hand is far more rare than the club foot. We might notice while comparing the changes in the fifth digit of hand and foot that the comparative anatomists have considered that in the hand an extra post axial digit is represented by the pisiform bone while a similar but more completely lost postaxial digit in the foot is represented by a mere tubercle on the os calcis. As for the preaxial lost digits in normal limbs neither prepollux nor prehallux remnants are recognized. Hence the preaxial nerve group, or at least bone group, seems to be more dominant and the fore limb more stable than the hind limb. We might expect such a superior dominance in line with the development of the head and brain, at the upper end of the central nervous system, and the dropping of the tail and the coxygeal nerves at the lower end of the central nervous system.

The changes in the evolution of the race are also interesting. The study of the horse's foot we all have seen demonstrated in the museums of natural history. There the evidence is shown of the dropping of one digit after the other from the five toed horse to the one toed, until there is left a single large bone in the leg from knee to ankle, a single tarsal bone and a single ray of phalangeal bones. When we look at the human skeleton and compare the size of the tibia and the fibula and the digits beyond each of them it does not take much imagination to see suggested in the slender fibula and the diminutive little toes, an early stage in the reduction process which if carried farther would lead to a diminution of the number of toes on man's foot. In talipes equinovarus (the word "equinus" is full of meaning) we have the partially developed foot in which the muscles are least developed and the bones incompletely developed also and at times we find a shortened fibula and absence of the little toes. It may not be wandering too far astray from the idea of the control of tissue development and growth by the central nervous system to call attention here to some case reports on autoamputation of the little toe, called ainhum, and the evidence which suggests that ainhum be classed as a lesion with its origin in the central nervous system. (See MEDICAL RECORD, March 18, 1911.)

To gather together then our ideas on the cause of club foot which our text books tell us starts with the inheritance of a family trait, we recognize the symmetry of the lesions, the association with multiple congenital deformities of brain, spinal cord, and limbs, the close analogies with dropping of digits in other species, the anatomical changes in the structure of the leg suggesting an underdevelopment of the postaxial ray in the leg. We come thus to the suggestion of club foot as a tendency toward the dropping of the postaxial digit group of the lower limb. And this dropping of a digit group would seem to be due to restricted development in the central nervous system—a factor that has been at work since before the days of the five-toed horse.

STONELEIGH COURT.

Medicolegal Notes.

Payment for Services Rendered Injured Employee.—In a surgeon's action against railroad contractors for services rendered an injured employee, evidence that the person who wrote a letter obligating the defendants to pay for the expense of the employee's treatment was defendant's timekeeper, and that he signed checks, attended to correspondence and signed letters for the defendants, was held to authorize the jury to find that he had authority to sign the letter. The injured man was sent to a hospital for treatment with the contractors' knowledge of their obligation to him. The plaintiff, besides having charge of the patients in that hospital, was the railway company's physician. He treated the injured man. The contractors, after the railway company found the man was not one of their employees, wrote the railway company acknowledging liability for the expenses of the hospital services. It was held they were liable to the surgeon for the entire services rendered by him, not merely for those rendered after the date of the letter. The fact that the contractors collected a fund out of the wages of employees to enable them to care for and furnish medical aid to anyone who might be injured did not necessarily make them liable to the surgeon for his services to the injured employee. but it was a proper circumstance to be considered by the jury. Judgment for the plaintiff was affirmed.—Perkins vs. Kilpatrick (Mo.), 193 N. W. 876.

Evidence as to Physician's Earning Capacity.—In an action for personal injuries to a physician and surgeon while a passenger on a car which stopped so suddenly that he was thrown down, it appeared that he was in hospital for some time and disabled from practising for over two months, and, as he testified, was permanently injured. On appeal from a verdict and judgment for $40,000 it was held that although he testified that he could not give a definite idea of his cash receipts for a month or any period of time, but thought, without having examined his account books for previous amounts, that his income for the two months would have been $2,000 a month. that the question of his earning capacity was for the jury, and the judgment was affirmed.—Graul vs. United Rys. Co. (Mo.), 193 S. W. 38.

Transactions between Physicians and Patients.—It is undoubtedly the rule that any transaction between a physician and patient inuring to the advantage of the former will be closely scrutinized, and stricter control over it will be exercised than in cases where no such confidential relation exists between the parties. The precept, however, does not go so far as to constitute a medical man a guardian for his patient, and it is not enough to say that he merely had knowledge of the action of a third party against whom the patient seeks relief without showing also that the physician participated in such action.—Ulbrand vs. Bennett, Oregon Supreme Court, 163 Pac. 445.

Military Medicine.

VENEREAL DISEASES IN THE WAR.

(From Our Regular Correspondent.)

PARIS, June 19, 1917.

IN the series of letters which I have been privileged to write to the MEDICAL RECORD I should feel that I had signally failed in a great duty if I shrank from exposing to my medical colleagues (as much as I dislike to do so) the dangers that lurk in beautiful France to engulf the unsuspecting American soldier, and I dread and fear that bodies crippled by wounds and lost limbs are not the worst that will be brought back to the New World, fair America; and it is to do what I can to awaken my colleagues coming to service in France to the widespread danger to which our troops will be subjected, far more dangerous to American national life than any war devices of the enemy, that I bring to their knowledge certain statistical information respecting syphilis in France at the present moment.

There are fewer than fifteen thousand doctors in all of France, and more than two-thirds of these are mobilized, and more than one-half of those are at the front. More than two thousand, since the beginning of the war, have been killed, wounded, or made prisoners. Only a few weeks ago six hundred were returned from Germany via Switzerland, in exchange. It will readily be seen that civil practice and the civil service in the hospitals is sadly in need of doctors. Being a graduate of the French Medical School, and legally entitled to practise in France, I was, more than a year ago, assigned to a civil hospital position in addition to my military service, that civil work being in the section of the Cochin Hospital devoted to syphilis. More than 5,000 cases have passed through our clinic in twelve months; but it is not to my own service I shall refer for my statistics, but to that of Professor Gaucher, who, outside of my own chief, Fournier, is one of the best known in this specialty in Europe.

In a recent publication (*Paris Médical*, January 20, 1917) Professor Gaucher writes as follows: "Whereas, before the war, in round numbers, out of 3,000 clinical patients 300 had syphilis, or 1 in 10, during the first months of the war these increased to 800 in 5,000, or 1 in 6. During the last eight months of 1916 this increased to 600 in 2,300, or 1 in 4. I therefore find that from August, 1914, to the end of December, 1915, the ratio of syphilis had increased more than one-third, and from January to August 1, 1916, it had increased more than one-half, and since then has advanced to nearly two-thirds of the clinical cases that present themselves in the service."

This rapid increase in this disease is carried out by the reports of the Clinical Service at St. Louis Hospital, which is one of the most celebrated, where, before the war, out of 300 to 400 coming daily to the outdoor clinic, four or five were syphilitic. At this present time, twelve to fifteen appear in the same number, and it is a deplorable fact that everywhere reports show an increase of from one-half to two-thirds in this disease since the outbreak of war.

Professor Gaucher further expresses himself: "Venereal diseases are still considered a subject about which one should keep silent and never speak. This hypocrisy is full of danger, and steps should be taken to warn both civil and military against the present danger. Happily, during the present year great progress has been made in this respecting the military. Conferences have been organized all along the front and among the reserves respecting venereal diseases, by the heads of the hospital service and the medical chiefs of troops in the field. This is due to the initiative of my military chief, the incomparable organizer and initiator, Inspector-General of the Medical Corps, General Sieur, who arranged twenty-two conferences in the Paris district, with lantern slides and lectures, which were attended by 8,000 of the troops, delegates from various arms of the service, and five similar conferences for 1,500 officers, with the hope to prove the truth of the old axiom, 'Once warned is twice armed.'"

If these men, and also women, had not been brought up in complete ignorance of everything pertaining to sexual life, but taught in youth to care for and safeguard themselves, the present deplorable state of affairs would not exist.

The space of this letter permits only of one cardinal warning to be remembered and communicated by the front-line surgeon to the soldiers and officers coming to Paris on furlough.

It would seem that all the loose characters in the country have congregated, since the war, in Paris. The railway stations at which the men arrive from the front are infested by lewd women, who have located their quarters as near to these sections as they can; as a rule, they are well dressed, perfumed, good-looking, and mostly young. They thoroughly understand reading the faces and make-up of the newly arrived, and seek him coyly or openly, as they decide most likely to succeed. There is only one safe rule: Warn the soldiers under your care not to have anything to do with any woman who can be picked up on the street anywhere.

146, AVENUE DES CHAMPS-ELYSÉES.

PROTECTIVE INOCULATION AGAINST GAS GANGRENE.

THE prevalence since the early days of the war of gas gangrene has greatly quickened interest in the bacteriology and pathology of this condition, but the views hitherto put forward have been mainly theoretical. The treatment has, in consequence, been somewhat empirical, and rather barren of results. It is known, of course, that the infection was with a microorganism of the Welsh bacillus group, but the pathogenesis of the condition has been variously interpreted. Among the different views held have been that the symptoms, both local and general, are caused by an acidosis; that the necrosis is produced mechanically by pressure of the gas; that the systemic effects are the result of absorption of endotoxins or of the products of decomposition of the tissues; in other words, that the fatal results are due to an acidemia, an endotoxemia, or a sapremia. As we have said, all these explanations are purely theoretical, not proven by experiment, and not sustained by the results of treatment.

A much more satisfactory interpretation of the symptoms of gas gangrene is offered by Carroll G. Bull and Ida W. Pritchett in their account of a

number of inoculation experiments made at the Rockefeller Institute, published in the *Journal of Experimental Medicine* of July 1, 1917. In their studies they used five cultures of the Welch bacillus, four of which came from infected wounds in the present war. The inoculations were practised upon pigeons, rabbits, and guinea pigs, the former being the most susceptible, and were made intravenously and intramuscularly, the effects produced by the two differing markedly. From the results of these experiments the authors came to the conclusion that "infection by *Bacillus welchii*, like infection by *Bacillus tetani*, essentially resolves itself into an intoxication in which an exotoxin yielded by the multiplying organisms constitutes the chief danger. The two conditions differ, however, with respect to the local effects produced on the tissues, since the tetanus toxin does not possess inflammatory and necrotizing properties. The Welch bacilli, therefore, grow more abundantly and produce wide destruction of tissue, in which process they are soon assisted by the usual pyogenic microorganisms which quickly obtain a foothold in the disorganized structures." As in the case of tetanus, the cause of death in gas gangrene is not a bacillemia but an intoxication with a virulent toxin produced by the specific microorganisms in the tissues. This toxin is a complex body, consisting of a hemolysin and another poisonous element which of itself may cause death without erythrolysis.

Having thus determined that the gas bacillus, like those of diphtheria and tetanus, exerted its pathogenic effects by means of an exotoxin, the authors naturally made inquiry into the possession by the latter of antigenic properties and into the possibility, therefore, of antitoxin formation. Two sets of tests were made, viz., the setting up of active immunity and the production of an antiserum, and both gave positive results. Successive injections of carefully graded filtrates of cultures of the Welch bacilli into pigeons and rabbits gave rise to active immunity, and the blood from the immunized rabbits neutralized toxic filtrates *in vitro* and *in vivo*. The filtrate is to be regarded, therefore, as toxin and the serum as antitoxin. The antitoxin is found to be protective, in pigeons, against infection with both the spore and the vegetative stages of the gas bacillus, and studies are now being made to determine the limits of its protective and curative action.

So far as they have gone, the results of these investigations seem to be eminently satisfactory and encouraging, and it is to be hoped that when put to the clinical test they may be found to be effective in the treatment of gas gangrene in human beings. Up to the present time the treatment of this condition has been empirical, and has relied largely on the oxygenation and consequent inhibition of anaerobic bacteria by means of continuous irrigation with peroxide of hydrogen or by other modes of permeating the infected wound with oxygen. Further investigations in this direction will be awaited with great interest.

Paramedical Work at the Front.—The term "paramedical" is used by Morin (*Journal de Médecine de Bordeaux*, March 25) to designate medical auxiliary activities. Upon the Service de Santé devolves the task of rapid evacuation of soldiers with major wounds to the rear. This is necessary for the *morale* of the troops. Nevertheless the execution of measures for this purpose is extremely difficult. To carry them out too literally is to defeat one's own aims. Yet system is of course indispensable in as far as it does not eliminate personal initiative and valor. Prudence and hardihood must go hand in hand. The medical auxiliary must be in as close touch as possible with the fractions of troops engaged in battle who will furnish the severely wounded and at the same time must keep in touch with the communications which pass from the fighting line to the *postes de secours* along which transportation is effected. The length of the communications is seldom less than 800 metres counting the windings of the passages. The stretcher bearers have to reckon with four components: 1. The weight of the wounded. 2. The length of the passage. 3. The nature of the passage. 4. The langers incidental to the trip. The more difficult the road the shorter should it be and the less hazardous. With diminution of danger as the porters leave the front and with a good sheltered thoroughfare adjacent a long stretcher trip may be practicable. Four men are required for a stretcher at the outset, or at the very least three. Two men never suffice because if the party is hit with bullets it might end transportation straightway. With extra members of the crew this is much less likely to occur. The principal reason for more than two men is, however, that the porters can work in short shifts and so expedite the transportation and return. The porters frequently have to take cover and dash from cover to cover. When overworked they may be unable to play hide and seek with machine guns.

In transportation from the fighting front trench-like cuts are largely utilized and these may readily be choked up. Special stretchers are utilized to negotiate these passages. Some of these are shorter than the patient, who must be borne with his lower limbs flexed on themselves or with his thighs flexed on the pelvis. The most ideal yet devised permits of transportation with the patient sitting. This pattern, however well suited for the narrower tunnels, is at a disadvantage in wide cuts and in free roads, and its use should therefore be restricted to static warfare. In aggressive drives they appear to be useless; for in this form of warfare men count for more than stretchers and the latter can be rapidly passed along by many shifts of men almost like buckets by a fire brigade. This plan works out admirably, for the transportation is rapid, the porters do not become fatigued and efficiency has full play. There is abundance of room for precision without hopelessly sacrificing initiative.

When all is properly planned every fighting soldier knows who will transport him if he is wounded, and the porter in the ranks of the combatants is himself practically a combatant. Aside from this close relationship with the troops the porters are themselves organized, first in crews with a head porter, the crews being in turn organized into squadrons, which are directed by a surgeon or, in his absence, by an officer of their own. The porters in the course of an advance with the troops are never exposed unnecessarily. If a body of troops

is invested and threatened with capture, the chief executive of the porters orders them to stick to the wounded and maintain the communications to the rear. Under fire there is no maneuvering, for the one aim is to take cover previously in view for the purpose, so that the porters are not supposed to work under fire. Under the temporary shelter they first give attention to the wounded, and it is often possible to group and evacuate the severely wounded before the cover is abandoned. They are then in position to attend to the victims of the barrage fire, which include soldiers already wounded.

Reserve troops have their own porters. Orderlies and even regiment musicians may act as porters. Formerly machine-gun companies dispensed with porters, but at present some of them are thus endowed. One aim of porter service is to eliminate the slightly wounded men from clogging the *postes de secours*. Without such service the "fake" wounded would also secure transportation. Any soldier so injured as to be unable to help himself has his wound painted with iodine and receives an occlusive dressing. Tournequets and retentive apparatus are available when needed.

Transportation may be hampered or rendered impossible by barrage fire, machine gun activities or investment by the enemy. In such cases the wounded must be grouped in shelters—five being the usual limit—until nightfall or cessation of enemy fire. One man, or perhaps two, could be overlooked, but this could hardly occur if the group comprised more, for some one could give the alarm. The reader will perhaps wonder if the stretchers get back to the front, and if so how this is accomplished. It is evident that they must often be bloody and dirty. There is supposed to be a sufficiency of stretchers at the start—often a burdensome excess. When relays are used, clean folded stretchers are readily passed along from the rear to replace soiled ones. Porters when they drop out wounded have their places filled by orderlies or porters from the reserve troops. Relay men are never disturbed, for obvious reasons. The captain of all the regiment porters, whether an auxiliary physician or layman, not only supervises the activities of his subordinates, but keeps watch for wounded soldiers. His duties are very hazardous. The battalion physician supervises the slightly wounded, aided by his immediate staff, and sees that attests are duly made out. He also inspects the severely wounded after their injuries have been dressed. Naturally his watchfulness extends over the state of the communications; in fact, he neglects nothing which bears upon proper care of the wounded.

Fitting the Mutilated for Agriculture.—Thus far perhaps only such armless men as had previously followed the profession of agriculture have been fitted with prosthesis suitable for their occupation and as two-thirds of all thus mutilated were originally tillers of the soil the manufacturers of artificial hands and forearms will long have their work cut for them in this class alone. Yet so great is the need for agriculturalists that many armless men not originally farmers may be so equipped as to be able to do certain kinds of farm work. At present many mutilated men are in doubt as to which activity to take up and the medical profession have excellent opportunities to recommend this course. Charmot, in a graduation thesis (Lyons) published last year, has supplied much useful information along these lines. It has already been stated that two-thirds of the mutilated are agriculturalists and he adds that two-thirds of these have mutilations of the upper extremities. If one-third of the upper extremity remains useful prosthesis is possible. Naturally, a considerable interval must be allowed for reeducation, but this movement has long been under way. Last August there were competitive trials by instructed men in spading and mowing. In regard to digging the surprising fact was noted that men with full arm prosthesis did better work than men with forearm prosthesis and normal men. Such efficiency means that the movements required are much more simple and limited. Men with both types of prothesis could mow 4 ares (about 1/10 acre) in about an hour.

The socalled Jullien tool, affixed to a temporary artificial arm, was used in all the competitive tests. Lyons has in fact become a center for the reeducation of these mutilated workers. Making allowance for the fact that speeding up is inseparable from competitions the results were none the less remarkable. As an offset may be mentioned that the competitors suffered from certain drawbacks. The first experiences are difficult and cause much fatigue. The prosthesis is not permanent. They are depressed naturally, and the first reaction is one of increased depression. They must not be worked too hard and the attitude of those over them should be a sympathetic one.—*Journal de Médecine et de Chirurgie Pratiques*, February 20, 1917.

Commissioner for American Red Cross.—Major-General Pershing has selected Major G. M. Murphy of the St. Louis Army Medical Unit as member of his staff to be commissioner for the American Red Cross in Europe.

Dr. Alexis Carrel of the Rockefeller Institute of Medical Research recently arrived from abroad at an American port on a French line steamship. It is stated that Dr. Carrel and his associate, Dr. H. D. Dakin, will instruct classes of American surgeons who are going to attend to the American wounded in France.

Insurance or Pensions for Soldiers.—Secretary of the Treasury McAdoo has opened a conference at Washington with reference to the subject of possible insurance for American soldiers and sailors. There seems to have been some suggestion of insurance as an alternative to pensions after the war. The comparative advantages of this talked of change will be a subject for consideration by Congress. It has been suggested that pensions based on the system of life insurance policies would solve the problem. That is, the pensions could be paid on stated conditions to the beneficiary as are life policies. A pension could be provided by act of Congress to the soldier or sailor during his life after his discharge at the end of the war; if disabled and unable to work, a proportionately larger amount could be granted; and in case of death while in the military service of the country a pension of a stated amount could be made payable to a person or persons designated

by him at the time of his enlistment. A simple but definite system could thus be developed and would remove the pension system from politics and at the same time insure peace of mind to the men with dependents and who have entered the United States services.

Sanitary Corps for Army.—Secretary Baker has approved an order creating a sanitary corps under the Medical Department of the Army which will include various classes of experts in sanitation, bacteriology, sanitary engineering, and men skilled in supplies, transportation, storage, etc., in connection with medical department work. Creation of this corps will make possible taking over intact hospital and ambulance units already organized in France which, under the law, can not be incorporated in the medical corps, to which the law authorizes the appointment only of graduates in medicine. This will allow the medical corps to make use of other trained men not graduates in medicine. The order creating the corps is as follows: "The President directs that under the authority of the first proviso of section 2 of the act 'to authorize the President to increase temporarily the Military Establishment of the United States,' approved May 18, 1917, there be organized under the Medical Department for the period of the existing emergency a sanitary corps consisting of commissioned officers proportionately distributed among the several grades as in the Medical Corps now established by law, and such enlisted men as the Secretary of War may determine to be necessary. The total number of officers in said corps may be approximately equal to, but not exceed, 1 for every 1000 of the total strength of the military forces authorized from time to time pursuant to law. The officers of said corps will be provided by assigning officers of the Medical Reserve Corps thereto, or by the appointment of citizens of the United States who are found under regulations established by the Secretary of War to possess special skill in sanitation, in sanitary engineering, in bacteriology or other sciences related to sanitation and preventive medicine, or who possess other knowledge of special advantage to the Medical Department. There shall be no grade in the sanitary corps above that of major and no officer of the Medical Corps shall be appointed in the sanitary corps. The number in the several authorized grades of the sanitary corps shall be proportional to the number authorized by law for the corresponding grades of the Medical Corps."

Red Cross Mission to Russia Departs with Speed.—The Red Cross Mission to Russia was organized, equipped with several carloads of hospital supplies, medical, and surgical supplies, first aid materials, etc., and started on its way within five days after designation of its members. The commission is composed of twelve men, including experts in medicine, public health, and social service. Not alone will immediate aid be given, but a study will be made of the most effective methods of giving relief to wounded soldiers and needy and suffering civilian population of Russia. The commission is headed by Dr. Frank Billings of Chicago and Mr. William B. Thompson of New York. As advisers go Raymond Robins of Chicago, Dr. J. D. McCarthy, professor of public health, University of Pennsylvania; Dr. George C. Whipple, professor of sanitary engineering at Harvard University; Prof. William S. Thayer, Johns Hopkins University; Prof. C.-E. A. Winslow, Yale University, and Dr. Wilbur E. Post of Chicago. Harold H. Swift of Chicago and Prof. Henry C. Sherman of Columbia University will manage the food supply question. The rest of the commission is composed of J. W. Andrews, Thomas Thacher, and Dr. Orrin Weightman.

United States Forces to Have Tuberculosis Test.—Since trench warfare in Europe quickly develops tuberculosis in men already infected with the germ, the War Department at Washington has completed arrangements to have all men drafted into the new national army, the present members of the National Guard and regular forces now in America especially examined for tuberculosis. It is assumed that the American forces now in France have undergone the special examination. All National Guard regiments will assemble at Southern camps, hence it will be necessary to draft physicians from other sections of the country to conduct the work on account of the large number of men brought together in the South. Col. George Bushnell of the Medical Corps, U. S. A. has been placed in charge of the special tests, and will be assisted by several hundred examiners. These men will be made members of the Medical Reserve Corps. The work will start with the National Guard and men in the officers' training camps about July 1, and will be continued with selective conscripts as the latter are called.

Dentists Pass Navy Tests.—Twenty-one dentists have passed examinations qualifying them for probationary appointment as dental surgeons in the United States Navy. The examinations required ten days and were both physical and professional. After two years' service in the Navy, probationary dentists are in line for a permanent commission, if their qualifications are proven. The salary is $2,000 a year, with $500 allowance when quarters are not furnished.

Women Give Hospital Unit.—The New York Infirmary for Women and Children, supported by the National American Woman Suffrage Association, New York City, has organized the first mobile hospital unit to be offered by the women of the country to the Government. The director of the unit is Dr. Caroline S. Finley, with an organization committee on which are Dr. Anna von Sholly, Dr. Mary Lee Edward, and Dr. Alice Gregory. The unit will have a force composed of about eighty women. It has now a nucleus of twelve doctors, twenty-one nurses, and three orderlies.

Presentation of an Ambulance.—The A. R. Elliott Publishing Company, publishers of the *American Druggist* and the *New York Medical Journal*, have presented an ambulance to the Montclair, N. J., Chapter of the American Red Cross.

Education of Crippled Soldiers.—Mr. Jeremiah Milbank has placed the building at Twenty-third Street and Fourth Avenue, New York, occupied many years ago by the College of Physicians and Surgeons, at the disposal of the Red Cross for the benefit of the Institute for War Cripples. It will be used for the training and readapting to industry of men permanently crippled and disabled by the war.

New York, July 14, 1917.

A DOUBTFUL EXPERIMENT IN HEALTH ADMINISTRATION.

FOR over a year the Department of Health of New York City has been carrying on an experiment of health administration on the district plan in the Borough of Queens. The essential feature of the plan is the establishment for each of the four sections, into which the Borough has been divided for the purpose, of a local health department with a medical officer at the head of it, under whose directions visiting physicians and nurses and sanitary inspectors carry on the work incident to school inspection, the supervision of contagious and communicable disease cases, attendance at clinics and milk stations, and food and sanitary inspection. It is a radical departure from the present form of organization in the Department of Health, with its many divisions and specialized functions. It is an attempt to break away from specialization in health work and to revert, as it were, to the small town idea where the manifold health functions are carried on by a health officer with his small local staff.

It does not recognize the need of specialized services, such as supervision of tuberculosis cases, of contagious diseases cases, school inspection, or baby welfare. It assumes that these forms of specialization are unnecessary and that every nurse is, or should be, able to perform all the functions incident to health work. It is an implication that the theory on which the health administration of New York City, and everywhere else, has been so assiduously built up is erroneous, and that over specialization has led to the loss of a sense of reality of the whole realm of public health work on the part of the agents of the Department. It is claimed that under the old departmental system no single officer of the Department of Health has a complete idea of the whole fabric and purpose of health work. It has also been stated that the bureau system led to a great deal of duplication of effort.

There is no doubt that there are arguments in favor of the district plan of public health organization aside from the fact that it is in line with the modern attempts of creating stronger civic sense through small community organization. No one will deny that there is a distinct need of bringing the Health Department of the city closer to the people, of facilitating its contact with the community, and of simplifying many of its procedures. There is need of district offices or health centers where the citizen can register his complaints or make application for the various kinds of permits he needs; and there should be local stations where the agents of the Department, working in certain districts, could report for duty and whence they could go out to perform their functions in the neighborhood. These local health stations might also house the baby clinic and the dental clinic and discharge other functions of the Department of Health. But all this is entirely distinct from giving administrative authority to local health officers. The plan as carried on in Queens, and as contemplated eventually for the whole city, creates a large number of independent administrative units and embraces the possibility of submitting the Health Department administration in the district to local political pressure. It also offers possibilities of substantial differences in discipline and in the emphasis laid on the various kinds of public health procedure.

Whatever the merits and demerits of the system, one thing stands our clearly—that this experiment, the value of which has as yet to be demonstrated to the public, should not be applied to any other borough except that in which it is now being tried. No changes of such sweeping nature as the almost complete decentralization of the City Health Department should be made at the end of an administration, when we do not know what results the November elections will bring forth. There is no reason for extending the plan to any other borough this year and there is every reason against it, particularly at this critical moment in our history when the physicians of the Department may be called upon by the Government for duty in addition to their Health Department work.

INCREASING RECOGNITION OF THE IMPORTANCE OF THE INVOLUNTARY NERVOUS SYSTEM.

THE old, much neglected sympathetic nervous system is rapidly and surely coming into its own. It is taking long strides forward in its march to the front ranks, where it is holding our interest in more and more clinical problems. Eppinger and Hess in their stimulating and very suggestive monograph on Vagotonia have given us a good description which applies in varying degree to a host of individuals whom many of us had been in the habit of labelling, in our lazy fashion, "just nervous," or of even attributing their complaints to "imagination"—and letting it go at that.

An interesting paper along this line is furnished also by Smith under the title of "The Relation Between Overactivity of the Vagus System and Anaphylaxis," in the *Journal of Nervous and Mental Diseases* for January, 1917.

The relationship of the involuntary nervous sys-

tem, with its two great antagonistic divisions, named the vagus and sympathetic systems or divisions of the vegetative nervous system, to the activity of the ductless glands and to many biochemical phenomena, even what is now being referred to as acidosis, is being developed here and there. Many paroxysmal conditions, for which it was difficult for us hitherto to offer a satisfactory explanation, are now being reexamined in the light of our newer viewpoints and concepts, and the reflected light derived from the newer studies on the involuntary nervous system is now being permitted to illuminate many dark places. The reactions to many drugs are now understood and explained with the help of the newer knowledge of the involuntary nervous system. Here we may mention atropine and the belladonna group, adrenalin, pilocarpine, physostigmine, muscarine, choline, and the like. Serum sickness and the reactions to all sorts of foreign proteins (including those derived from bacterial infection, acute and chronic), are being viewed from this angle.

From this standpoint, too, we are now beginning to look upon many of the symptoms due to intestinal parasites, the reactions found in the many food idiosyncrasies, and the phenomena observed in asthma, hay fever and spring catarrh, juvenile emphysema and eosinophilic catarrh, mucous colitis, urticaria and angioneurotic edema, and many other allied conditions. The explanation of even migraine, if approached from this angle, is much simplified when we bring it into relation with localized instability of the involuntary nervous system.

The method of action of the emotions and psychic stimuli—trauma and shock of all sorts—in producing their many visceral disorders, can now be appreciated. The effect of toxins and of the ductless glands is so much the better grasped.

The whole problem of anaphylaxis, infection, and immunity is now being attacked with these new weapons in hand. Here, too, let us not forget to mention the symptomatology which we come upon at puberty, the menopause, and some of the vague complaints found in the aged.

THE RATIONALE OF THE CARREL METHOD.

ALTHOUGH what is known as the Dakin solution is admitted on all hands to have had really remarkable results in cleansing and disinfecting infected wounds, perhaps, the technique of administration thereof devised by Carrel has been the chief cause of its unprecedented success. Even saying this might be going too far; it is the laying open of infected wounds, combined with the Carrel technique, that has rendered Dakin's solution so effective. Most of if not all surgeons at the front unite in stating that infected wounds must be laid completely open; this is the essential procedure. Many surgeons who lay extreme stress on the point, however, are by no means enthusiastic concerning one or any antiseptic in treating infected wounds.

The Carrel technique has been so often described that we need not repeat the description here, except to say that the object of the method is to instil, continuously or intermittently, the Dakin solution into all the recesses and anfractuosities of the wound, into which it is conveyed by fine rubber tubes. The intermittent method is the one generally used, because the continuous instillation, drop by drop, is too tedious for employment, as a rule, under war conditions. The technique is regulated according to shape, location of wound, and so on.

The solution employed, while mildly antiseptic (the reason why it has to be employed more or less continuously for a protracted period), is comparatively innocuous to healthy tissue. Scientifically controlled and measured by the technique devised by Carrel, Dakin's solution appears to fulfill the main postulates of the ideal antiseptic. It disinfects the wound and does not injure healthy tissue, but it is possible that this result may be due to the technique and the opening up of the wound thoroughly, rather than to the solution itself; and it may be that other antiseptics, if employed in the same way, would have much the same effect as Dakin's solution. Personal cleanliness of the surgeon, and especially of the hands of the surgeon, was preached and insisted upon by Pasteur and Lister, and now, as Defosses says in the *Medical Press*, May 30, 1917, Carrel has taught surgeons to wash wounds. Carrel, in fact, has taught surgeons the only effective manner in which a mild antiseptic can be used. A strong antiseptic defeats its own purpose to a great extent.

FUNCTIONAL MITRAL STENOSIS.

IN 1854 Stokes described a spastic form of mitral stenosis after Läennec had expressed the opinion that such an affection was theoretically possible. He was corroborated by a number of French clinicians, the prevalent opinion having been that the condition was due to a spasm of the papillary muscles. It occurred in the absence of a neuropathic disposition and without any increase in the volume of the heart; and its functional nature was especially betrayed by its inconstancy and variability. The question eventually arose, "is this spastic type the sole functional type?" or better, "is there not such a condition as a quasi functional stenosis which has a physical basis?" This question incidentally invokes the possibility of a mitral stenosis murmur without stenosis. These problems all deal with an isolated condition; for of course it is well known that a functional mitral stenosis may accompany aortic insufficiency.

In 1915 Rodriguez of Havana described a type of functional mitral stenosis which is discussed by Ferranini in *La Riforma Medica* for March 24. In this form there is actually stenosis present, but the murmur is transitory and heard only occasionally. The condition is due to a lack of elasticity in the atrioventricular ostium due to the presence of fibrous tissue which indicates a previous prolifer-

ative process of obscure nature—tuberculous or syphilitic. The left atrium shows dilatation, which also appears in the right ventricle, and the radial pulse occurs later than the apex beat.

Ferranini rejects this disease conception entirely, for according to its discoverer, it is a functional condition so called, with a physical basis. It may behave like a functional condition so far as the murmur is concerned, *i.e.* it may be an "acoustically functional" condition, but in general there is no essential difference between Rodriguez's disease and Duroziez's congenital mitral stenosis, because in the latter a murmur is not always audible. Moreover, the alleged causation is the same, as are also the physical signs—dilated left auricle and right ventricle, belated radial pulse, etc. Naturally Rodriguez should be heard in his own defense, and it is to be hoped that he will restate and amplify his conception of the new disease entity.

RADIOTHERAPY OF DEEP SEATED MALIGNANT DISEASE.

In the treatment of deep seated malignant disease, all surgeons and a very large number of physicians agree that in those cases in which the removal of the disease is possible it should be done immediately. Radiotherapy has not effected much in the case of deep seated cancerous growths, except so far as the uterus is concerned. However, John Macintyre, writing in the *Glasgow Medical Journal* of May, 1917, points out that notwithstanding all the skill of the great operators, there is always the possibility of the invasion of the lymphatics for a considerable distance, it may be, for example, through the chest, where the secondary disease cannot be got at by the surgeon. Many surgeons, therefore, by way of prevention of recurrences, introduce tubes of radium into the wound immediately after an operation, and give a sufficiently strong dose to destroy any small portion which may have been missed or which is beyond the reach of the knife.

But in judging of the value of these agents, attention should be drawn to the fact that the stage which the growth has reached and the state of exhaustion may mean that success cannot be hoped for from the application of radium or *x*-rays. For this reason Macintyre has always classified cases of malignant disease under observation, whether treated by the *x*-rays or radium, into four classes: (1) Those which have had treatment and there is no return of the affection. (2) Those cases in which the disease may return once or twice or oftener, but in which it is ultimately controlled. (3) Cases in which we can hope only for amelioration and prolongation of life. (4) Cases in which neither radium nor any other agent is of the least avail.

Thus the experience of Macintyre leads him to the some conclusion as that of other radiologists, that radium and the *x*-rays are in the treatment of deep seated malignant disease by themselves of little use, except in the case of the uterus, but that as adjuncts to surgery they are not infrequently of great value.

Medicinal and Nutritive Properties of Yeast.

Yeast has been found to be rich in vitamines; in fact, it contains an enormous amount of the antiberiberi vitamine. Dr. Morris Stark, in a paper contributed to *American Medicine* for November, 1916, states that cases of pellagra which were treated with autolyzed yeast under his direction showed either a very rapid improvement or else complete disappearance of symptoms in a very short time. The antiscorbutic value of yeast has not been so decidedly proved, although Allan Brown is cited by Stark as stating that autolyzed yeast is of very considerable antiscorbutic value if used in sufficient dosage. Moreover, in the case of rickets in a nursling, it is said that autolyzed yeast has been administered to the mother with good effect on the child, or it may be given to the infant itself. Yeast has been employed with benefit in the treatment of certain skin affections, and is said by some to have a quite wide therapeutic range. Dried yeast, as pointed out by Baruch in the Medical Record of June 16, 1917, has been combined with straw in order to increase the nutritive value of the latter as fodder. The experiments conducted to determine the medicinal and nutritive value of yeast seem to show that it possesses considerable merit in both directions. Its chief value, however, probably lies in its high vitamine content, rendering it, on the whole, one of the most efficient remedies in our possession for the treatment of beriberi, and possibly also of pellagra. The argument that yeast has such a high nutritive value that breweries should be continued mainly for its production will, however, hardly hold water, or even beer.

Tuberculosis in France.

For many years tuberculosis has been more prevalent in France than in, perhaps, any of the European countries, and the conditions of trench warfare have been responsible for a vast increase of the disease among French soldiers. At the beginning of the war the French were compelled to defend themselves without much aid from the British and Belgians, and in consequence could not be very particular as to the physical fitness of their men. Tuberculosis is, therefore, rife among French soldiers, and although the authorities are doing their best to repair the results of the early neglect of careful examination, and are removing all tuberculous soldiers as quickly as possible, the problem of tuberculosis in that country is extremely serious. It has been announced recently that the Rockefeller Foundation with the approval of the French Government and in cooperation with the American Red Cross is about to take steps with a view to curbing the spread of this disease in France. It is understood that the work will be carried on under the supervision of a French central committee and local committees which are being organized throughout provincial France. From all points of view the scheme of the Rockefeller Foundation to restrict the ravages of tuberculosis in France is most meritorious. Not only is it giving powerful aid to a brave ally, but it is helping to lessen a danger to which our own troops will be exposed when they reach French soil.

Plant Secretin.

In an editorial note on the pharmacological action of vitamines which appeared in the Medical Record of June 23 attention was called to the fact that vegetable vitamines had been nicknamed "plant secretin" (by the way, the printer caused this term to appear as "plant secretion"), because of its power to activate the secretion of the gastric glands and pancreas. According to an abstract in the *Hospitalstidende* for May 9 Bickel published in a recent number of the *Berliner klinische Wochenschrift* an article on a new plant secretin, but without reference to the vitamine nature of the latter. The excessive use of vegetable foods by the Germans during the present war has stimulated an intensive study into the complete food values of even the least nutritious plants. Bickel was able to isolate from spinach a substance which exhibited the power of animal secretin. It may be extracted by heat or digestion with HCl, but is destroyed at a temperature of 140 deg. C. Inert, practically, when given *per os*, "spinach secretin" exhibited parenterally can increase the secretion of gastric juice in the stomach pouch of Pawlow dogs. Its behavior recalls that of pilocarpine, but it may perhaps act further through the central nervous system.

News of the Week.

Restricted Diet for U. S. Cabinet.—The wives of the members of the Cabinet at Washington have become members of the food administration and have pledged themselves to one wheatless meal a day as well as serving beef, mutton, or pork but once a day, completely cutting out veal and lamb. Strict economy will be practised in the use of butter and sugar and, instead, fish, fruit, and vegetables will be served in sufficient quantity. Thousands of pledges are reaching the offices of the food administration. An effort is being strenuously made to enroll every woman in the country over sixteen years of age.

Warning Against Burma Bean.—The United States Department of Agriculture has ascertained that certain shipments of beans from the Orient known as Burma or Rangoun beans have entered this country through Canada. These beans to the ordinary glance resemble the navy bean but can be distinguished by their pale, yellowish color and the fine, distinct radiating lines passing out from the hilum or eye. They are pole beans of the lima type, but not suitable for planting here since they are tropical and will not mature in the bean-growing states. They are not fit for human consumption because they yield hydrocyanic acid in amounts sufficient to be injurious to the health of the United States public. The port and border laboratories of the Bureau of Chemistry are under instructions to make examination of all shipments of such beans offered for entry and to effect their detention.

Free Vaccination for the Public by U. S. Health Officers.—Secretary of the Treasury McAdoo has issued the following: To medical officers of the United States Public Health Service, and others concerned: Hereafter as a means of preventing the spread of disease either by military forces of the civil population, any person in the United States may receive, without cost, upon applying in person at those places designated by the Surgeon General of the United States Public Health Service, vaccination against any one or all of the following-named diseases: smallpox, typhoid fever, parathyphoid fever. Medical officers and others charged with the duty of performing such vaccinations should make requisition for the materials necessary therefor, and shall render a monthly report showing the names of those so vaccinated, their addresses, and the date of said vaccination. Upon the request of any person so vaccinated certificate of vaccination may be issued.

A Correction.—In the report of the Section on Diseases of Children of the American Medical Association, the issue of June 9, the title of Dr. Thomas S. Southworth's paper should be "A Familial Tendency to Fat Incapacity in Infancy and Childhood" and not a "Familiar Tendency." This misprint results in the loss of the main point of the author's paper which was to call attention to the fact that an incapacity to digest normal amounts of fats may be hereditary and in certain instances can be demonstrated in several members of the same family.

A Shoeless Nation.—The City Council of Zittau, Saxony, has appealed to its population to go barefooted because leather and shoes will be most scarce during the coming winter. The Wuerzburger student body has demanded of all students, male and female, that they either go barefooted or wear wooden shoes without stockings from June 28 on.

The War and Our Food Supply.—The *Food Bulletin* states that this food question has two parts: one to be solved collectively, and one to be worked out individually. To solve the collective problem New York City has been organized into 46 districts under the supervision of a central food aid committee, representing the School Board, the Mayor's Standing Committee on Foods and Markets and the Mayor's Committee of Women on National Defense. Every district has a central office in charge of an expert who will help on the special problems of her district whether these are reducing waste in the homes of the wealthy or of making more food available in the homes of the wage earners. There will be posted in the central offices lists of the food arriving in the city each day and its wholesale and retail price. If necessary the districts will open public markets and operate public kitchens.

Public Dehydrating Kitchen.—In New York City the Women's University Club, the Mayor's Committee of Women, and the Junior League have begun to can or dehydrate for the community the daily surplus of fruit and vegetables in the markets which would otherwise be wasted. The school lunch kitchen under Williamsburg Bridge has been secured for this work and sorting has already begun on the Erie Pier under the supervision of a committee of women, composed of voluntary workers. The food is shipped to the school kitchen, where canning and dehydrating machines have been installed, and under the leadership of a trained dehydrator, more volunteers preserve it. Each worker will receive a daily work card which will be redeemable in vegetables during the winter. In order to avoid waste it may be necessary to run both the work at the piers and in the canneries

night and day, which will necessitate four six hour shifts of workers. This is definitely a war work and the committee is requesting volunteers to send in to the Women's University Club their names and the number of weeks, days or half days they will be able to serve on the piers or in the cannery or drying kitchen. This is a valuable opportunity to do on a large scale for the community the same sort of work done individually in the home—to perform altogether an important war service.

Our Points of Economy in Food Rations.—At the present time all cereals are important war exports. During the first two years of the war 575,000,000 bushels of wheat were exported from this country and this year the Allies will require 1,000,000,000 bushels of cereals, half of which must be wheat. Hence for home consumption the patriotic food budget would substitute other cereals for wheat when possible—corn and rye bread, oatmeal, hominy, and rice. The two hinging points in the food budget are cereals and meat, as our Allies must have them, and so must we. Substitution is the accepted thing. All crop reports indicate an increased supply of fruit and vegetables. The fats needed by the armies will be lard, bacon, and salt pork; the housewife may substitute any available fat in home food budget. Sugar is another commodity sorely required by our men and neighbors across the water; our substitution here can be maple sugar and honey, of which 6 to 10 ounces a day will meet family requirements.

Feminine Governmental Aid.—A lament has arisen from the women of the land that sufficient opportunities for their services in the war have not been made by the Government. Their opportunity to make good has now come in their application of their energies to the dull, routine work of unending readjustment of the food budget and food supply. It may not be heroic but it will bring as sure results as the work demanded of the men in this time of stress.

Delay of Anti-Drug Law.—The New York State Department of Health has announced that the amendments to the State anti-habit forming drug laws, enacted by the Legislature this year, to become effective July 1, will not go into effect until August 1. The reason given for the original enforcement is an inability under the State finance law to contract in advance for the required printing to comply with the new law's provisions.

Aviation Relief Hospital.—Building of the Aviation Relief Hospital of the National Special Aid Society for the use of aeronautic section of the First Battalion of the New York Naval Militia, has been started at Bay Shore, L. I. The society has not only donated the hospital but also the needed equipment.

Bay Ridge Hospital Contract Given.—This hospital will be erected at Seventh Avenue and Ninety-second Street by the E. E. Paul Company. The main wing will cover the present erection and will cost about $135,000. Later the other buildings will be grouped around the main one, which will contain sixty beds, two free wards, an operating room, and several private rooms. The hospital will be open to all regular physicians and surgeons.

Leland Stanford Men Praised.—The ambulance section of the American field service of Leland Stanford University in France since last February has been mentioned in orders to the division by General Mougill for having shown courage and devotion in efforts to reach wounded at the battles of Verdun and Moronvilliers.

Franking Privileges Asked for American National Red Cross.—The Insurance Economics Society of America has been instrumental in introducing into Congress a bill which would extend the franking privilege to all mail indorsed "Official Business of the American National Red Cross." It is pointed out that inasmuch as the government is the beneficiary of all Red Cross effort, and inasmuch as the handling of Red Cross mail can be carried on by the government without cost, there is every reason why this bill should become law. It would stop the drain on the treasuries of local chapters.

Dr. Oswaldo Cruz, director of public health, Rio de Janeiro, died recently in that city, aged 46 years. Dr. Cruz was one of the foremost hygienists and bacteriologists of Brazil, and through his activity in preventive work he succeeded in three years in abolishing yellow fever and plague from Rio de Janeiro. In 1900 he established an institute of bacteriology and serum therapy in Rio de Janeiro, which in 1908 received his name, and which is one of the leading institutes of parasitology in the world. There Cario Chagas discovered the cause of South American trypanosomiasis, also called Chagas' disease, the organism of which was given the name *Trypanosoma* or *Schizotrypanum cruzi*. In 1908 Dr. Cruz instituted a crusade against malaria and smallpox in Rio de Janeiro. He also put an end to yellow fever as an endemic disease in Brazil. His efforts in the prevention of disease placed him practically as the national hygienic director of Brazil.

Obituary Notes.—Dr. Charles H. Howland of New Haven, Conn., a graduate of Yale University Medical Department, New Haven, in 1880, died suddenly in his office on June 26, from heart disease, aged 67 years.

Dr. Barton Dwight Skinner of Greenport, Long Island, N. Y., a graduate of the Bellevue Hospital Medical College, New York, in 1869, a veteran of the Civil War, and for nearly fifty years a practitioner in Orient and Greenport, died in the Eastern Long Island Hospital on June 22, aged 73 years. Dr. Skinner was visiting physician to the Eastern Long Island Hospital and was a member of the American Medical Association, the Medical Society of the State of New York, and the Suffolk County Medical Society. The last-named he had served for thirty-two years as treasurer, and had also filled a term as president.

Dr. Edward Howard died suddenly at his office in San Francisco, Cal., on June 12, at the age of 58 years. He was former chief surgeon of the Central Emergency Hospital, and at one time head of the Municipal Emergency Service.

Dr. Charles H. Whitman, superintendent of the Los Angeles County Hospital for the past eight years, died at his home in Los Angeles on June 15, at the age of 62 years. He was born in New York, but as a boy settled in the West, and graduated from the Bennett Medical College, Chicago, in 1886, and from the medical department of the University of Illinois in 1890. He was a member of the

Los Angeles Medical Society, a fellow of the American Medical Association, and past president of the Los Angeles Surgical society. He was also a member of the faculty of the College of Medicine, University of Southern California, and a member of the Southern California Psychopathic Society.

Dr. BURNSIDE FOSTER, a graduate of Yale and Harvard Universities, and student in several European universities, died at his home in Saint Paul, Minn., on June 12, after an illness of three months, at 56 years of age. He was former president of the Ramsey County Medical Society, a member of the Minnesota Medical Society, and a fellow of the American Medical Association, an editor for several years of the *Saint Paul Medical Journal*, as well as a clinical professor of dermatology and lecturer on the history of medicine at the University of Minnesota.

Dr. SOPHIE HARTLEY, 84 years old, died at Milwaukee, Wis., on June 15, after an illness of several months. She was graduated from the University of Michigan and practised in Ann Arbor for thirty years.

Dr. E. W. BROWN died at his home in Orange, Tex., on June 16, after a lingering illness, at the age of 59 years. He was graduated from the medical department of Tulane University, New Orleans, in 1882. He was Mayor of Orange for two years.

Dr. JAMES PARTRIDGE of East Missionary Ridge, Chattanooga, Tenn., a graduate of Chattanooga Medical College in 1909 and a member of the Hamilton County Medical Society, died on June 25 after an illness of several months, aged 46 years.

Dr. LOREN E. REX, a graduate of the John A. Creighton Medical College, Omaha, Neb., in 1899, died suddenly at his office in Wichita, Kan., on June 20, aged 41 years. Dr. Rex specialized in eye and ear work.

Obituary.

BROOKS HUGHES WELLS, M.D., F.A.C.S.

NEW YORK.

Dr. BROOKS H. WELLS died on Friday of last week at the Norwalk, Conn., Hospital, of fracture of the base of the skull, received in a collision with an automobile while he was bicycling on the road near his country home at Southport. Dr. Wells was born in New Haven, July 28, 1859, and was graduated from the College of Physicians and Surgeons, Columbia University, in 1884. From the first years of his medical life Dr. Wells devoted especial attention to gynecology, in which specialty he early won distinction. He was professor of gynecology at the New York Polyclinic, and gynecological surgeon to the Polyclinic Hospital; associate surgeon to the Woman's Hospital; consulting surgeon to the Brattleboro, Vt., Memorial Hospital and to the Beth Israel Hospital, New York City. He edited the translation of Pozzi's "Treatise on Gynecology," and for twenty-five years had been editor of the *American Journal of Obstetrics and Diseases of Women and Children*. He was a fellow and vice-president of the American Gynecological Society, a member and ex-president of the Medical Society of the County of New York, and a member of the State Medical Society, the New York Obstetrical Society, the New York Academy of Medicine, and the American Medical Association. He was recently commissioned captain in the Medical Reserve Corps of the Army.

Dr. Wells was, despite his confining labors as editor and practitioner, a follower of the outdoor life; he was fond of riding and wheeling, and was an enthusiastic yachtsman, often spending many weeks sailing along the New England coast. His summer home was at Southport, Conn., where he had passed his boyhood. He married Miss Mary Frances Pomeroy of Southport soon after his graduation, and is survived by her and four daughters.

HERBERT MAXON KING, M.D.

LIBERTY, N. Y.

ON the morning of June 24 Loomis Sanatorium lost its chief and medical director, Herbert Maxon King. Although he had been a tuberculous invalid for many years, Dr. King never ceased work until a few weeks before his last and fatal illness. During the past fifteen years he had had a number of exacerbations but always recuperated from them enough to resume work. The last, however, was complicated by a meningeal involvement from which he failed to rally.

Dr. King was born August 11, 1864, in Adams, N. Y., and was thus in his fifty-third year when he passed away. He graduated from Dartmouth College in 1884 and took his medical degree at the New York University in 1886. He engaged in general practice in New York, became much interested in laryngology and was made instructor in the New York Post-Graduate Medical School. He served for some time in the Marine Hospital Service, and after his resignation from the Government service he took up general practice in Grand Rapids, where he became one of the leading practitioners and attending physician to the Butterworth Hospital.

In 1902 he went abroad to visit and study the European sanatoria so as to be better prepared for his work at Loomis Sanatorium, for the directorship of which he had been chosen that year. On his return from Europe he entered upon his new task with energy and enthusiasm and with a thorough scientific knowledge and medical training. Under his guidance and direction the institution soon rose to be one of the best tuberculosis sanatoria in this country, if not in the world. Building after building was added. Dr. King had the faculty of interesting wealthy people in his great work. An annex for the poor who could pay only a small sum, with a number of endowed free beds for those who could not pay anything, an intermediate division for those of moderate means, an infirmary for the patients needing special medical care and supervision, a number of beautiful cottages, and lastly, a medical building with modern laboratory facilities, were the additions which the Loomis Sanatorium owes to Dr. King. Thus, the three divisions can accommodate at this time no less than 175 patients.

Dr. King's influence as an authority on tuberculosis and as a worker in the antituberculosis crusade has been widely felt throughout the United States. He has made many valuable contributions to tuberculosis literature, among them the article on "Tuberculosis" in Forchheimer's "Therapeusis of Internal Diseases." He was a member of the

New York Academy of Medicine, the National Tuberculosis Association, and many other scientific bodies.

Dr. King was a unique and striking personality. His patients worshipped him and believed and trusted in him implicitly. Many a one has told me that he had felt better after having seen and talked with Dr. King, who seems to have had the power to instill hope for recovery into every patient with whom he came in contact. His associates, friends, and pupils were devoted to him, and with his board of managers his word was law, and seldom if ever did they refuse him a request. They knew his intense interest in the institution and in his patients and that it was his ambition to make Loomis an ideal institution.

Though relatively young in years, Dr. King's life had been full of achievements. His memory will be cherished by thousands whom he has helped on the road to recovery and by the many friends and coworkers whom he inspired by his enthusiasm and devotion to medical science.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

EXCISION FOR GUNSHOT INJURIES—POISONING BY RHUBARB LEAVES — SPECIALIZATION IN ARMY PRACTICE.

London, June 16, 1917.

Gunshot injuries are much to the fore at the present time and the operation of excision is struggling for a return to the position it formerly held in military surgery. In older wars, no doubt, operations were performed for what would now be regarded as injuries scarcely severe enough or extensive enough to demand so radical a procedure. Moreover, wound treatment is often defective. Excision occupied a prominent place until, with the introduction of the bullet of small caliber or dome-shaped tip, injuries of the joints began to be regarded as of minor importance. A revulsion of opinion about this occurred early in the campaign and some surgeons have endeavored to enlarge the sphere of the application of this operation. Experience shows that it may be resorted to in well-chosen cases in all three stages of the progress of a joint injury with a distinct prospect of success under suitable conditions. This implies immediate operation at the casualty station. A certain number of joints may be excised as an alternative to amputation. Comminuted fractures of the upper end of the humerus and of the femur form good subjects for operation. On the elbow a partial excision may often be done. For these procedures the patient must be in condition to bear safely the risks of transport to the general hospital. Intermediate excision must only be undertaken with the definite intention of following it at once by an amputation if the procedure is at once succeeded by local extension of infection and signs of systematic absorption. But excision may be successful as an alternative when the severity of general and local signs indicate amputation as probably the only resource. The explanation of this seems to be in the fact that better drainage can be ensured when the articular ends of the bones have been removed and the wound can be treated more effectively. It is a striking fact that progressive osteomyelitis from the sawn ends of the bone has not developed, especially when the frequency of this complication in ill-drained comminated fractures is remembered. Two special details should be mentioned: (1) Should the synovial membrane be removed? As a rule the answer to this is negative. The synovial surface in itself is better able to deal with an infection than a freshly cut layer of subsynovial areolar tissue; further, when no extensions of suppuration have taken place it forms an effective barrier against such extensions when proper drainage is provided. (2) Should the refreshed bone ends be placed in apposition or be temporarily kept widely apart by extension? The latter plan has been more frequently adopted. The excision of bone should be of the most limited extent in the case of the knee. In this, as in all other joints, excision is not to be regarded as a proper alternative where efficient drainage can be expected to ensure the desired end.

Several cases of poisoning by rhubarb leaves have been reported lately. This is no new experience. As a substitute for spinach, these leaves have long been employed, but those who use them are generally acquainted with their disadvantage. At the inquest this week on a clergyman who died soon after eating cooked leaves it was stated that analysis showed oxalic acid salts were present to the extent of 10 grains to the pound. Dr. Spilsbury attributed the death to poisoning from this and said that in the ordinary way 20 grains to the pound might not be sufficient to cause death, but that amount would be on the border line and might affect some persons while others might escape. Though the use of the leaves as a vegetable is inadvisable, the stalk may be used provided that no soda is employed in the cooking. For a century or more the stalks have been used on an enormous scale as a substitute for fruit and have come to be looked upon almost as the fruit itself. In some very rare cases of idiosyncrasy every part of the plant seems to disagree. In all cases the leaves should be rejected.

Specialization continues to develop in all directions and in military medicine and surgery has increased so far that the authorities have found it desirable to establish special centers for cardiac, cutaneous, and venereal diseases as well as for compound fractures of the thigh and the treatment of disabled men in orthopedic hospitals or in curative workshops. Professor Strauss has suggested special hospitals or departments for cases of gastric disorder and chronic dysentery. He would also like to see special wards for trench nephritis.

Military Epidemic of Poliomyelitis.—Etienne saw an epidemic incidence of acute myelitis in twelve soldiers in a single hospital service. The disease was of the Hiene-Medin type.—*La Presse Médicale.*

Tests of Cardiac Aptitude for Effort.—Lian makes use of the genuflection test, 10 or 12 during a period of 5 seconds, and compares the pulse with the count before the test. The acceleration should disappear after two minutes or earlier.—*Journal de Médecine de Bordeaux.*

1. Loss of Sight from Posterior Accessory Sinus Disease, with Report of Three Cases. Leon E. White.
2. On Cranial Measurements of Persons Dying in Insane Hospitals. Lawson G. Lowrey.

1. Loss of Sight from Posterior Accessory Sinus Disease, with Report of Three Cases.—Leon E. White states that cases of retrobulbar neuritis can be divided into three classes: (1) The acute ones which usually follow the grip or a coryza and are accompanied by severe pain. The pressure of the secretions in the sinuses and the swelling from the inflammation in the mucosa cause construction of the optic nerve and artery. (2) The chronic ones where there is less pain, if any, and where an empyema of one or more sinuses is causing either a pressure on, or a toxemia of, the nerve. (3) Those cases where, on opening the sinuses only a thickened mucosa is found. Here hyperplastic changes are taking place and a periostitis in the sinuses by extension through the optic canal becomes a perineuritis. Patients with retrobulbar neuritis demand most careful attention. The diagnosis is made largely from the findings of the ophthalmoscope, vision and the visual fields. Radiographs may be helpful and should be taken, for even though they show no diseased sinuses, they may show some peculiar abnormality or some faulty development which might predispose to nerve involvement. Enlargement of the blind spot is another valuable and early sign of neuritis. The prognosis is, on the whole, favorable, especially where treatment is initiated before optic atrophy occurs. The success of any treatment must be based on a recognition of the pathology. Each case should receive individual treatment as no line of treatment is suitable for all. Some would get well without any treatment; other cases may clear up under appropriate general treatment, while severe cases demand careful and skilled medical and surgical treatment.

9. Infantile Pyloric Stenosis. J. Epstein.

1. Summary of the Wassermann Tests done during 1916 in the Philadelphia General Hospital.—Randle C. Rosenberger, director of the clinical laboratory of this hospital, states that from the men's medical ward, where it is almost routine, 1,097 specimens of blood serum were examined, and 259, or 23.5 per cent., were positive. From the women's medical ward, 273 examinations were made with 103 positive, or 37.7 per cent. In 273 submitted from the men's and women's surgical wards, including eye, orthopedic and dental, ninety-two were positive, or 33.3 per cent. The cases in the psychopathic wards included all types of mental cases under observation, toxemias of pregnancy, manias, dementias, including precox, paresis and paranoia, and traumatic and alcoholic confusional insanities. In all, 906 specimens of blood were submitted and of these 198 were positive, or 21.8 per cent. Of the 432 specimens obtained from the nervous wards, 103 gave a positive reaction, or 23.8 per cent. Gynecological cases numbered sixty-nine, of which twenty were positive, or 26 per cent., and of fifty-eight from the men's venereal forty-five were positive, or 75.8 per cent.; 278 were examined from the women's venereal and 127 were positive, or 45.7 per cent. A series was also obtained from the wards of the tuberculosis department. Of these 291 specimens were examined, ninety-eight, or 33.6 per cent. of which gave a positive reaction. From the children's department there were only fifty-six examined, of whom eight, or 14.2 per cent., were positive. Maternity cases numbered 136, of which ten were positive, or 7.3 per cent. In 561 specimens from the insane department, only 154, or 27.4 per cent., gave a positive reaction. Out of a total of 4,430 specimens of blood serum examined, 1,317, or 27.4 per cent. were positive. These Wassermann tests were done entirely by the technician, Miss McNitt. Rosenberger concludes that where an antigen is made carefully, and where titration is done regularly, where the control of each reagent used in the test is properly made, then there should be no great variation in the end result of this test.

3. Should the Colon Be Sacrificed or May It Be Reformed?—J. H. Kellogg, after an experience in the treatment of over 40,000 cases of intestinal conditions, during the past ten years at the Battle Creek Sanitarium, in which most of these patients suffered from intestinal stasis, has found that indications for surgical procedure are rare, and that nonsurgical means have brought permanent relief in the majority of cases. He has performed colectomy in but twenty cases, or less than one in 2,000. Kellogg takes the point of view that the colon, instead of being a useless organ, has a decided physiological place in the human economy, but that it has been badly treated by abuse through neglect, ignorance, and departures from biological methods of living. He offers the following nonsurgical means for relief in intestinal stasis: (1) A low protein, bulky diet consisting largely of fruits, fresh vegetables and whole grain preparations. (2) The free use of bran or agar-agar, or a combination of both, at every meal. From one half ounce to an ounce of cellulose daily seems to be necessary to stimulate the bowels to normal activity. (3) The use at every meal of half an ounce to an ounce and a half of liquid petrolatum. In some cases an emulson of liquid petrolatum gives more satisfactory results, and the best results are often obtained from the use of petrolatum (which melts at the temperature of the body). (4) Abdominal massage and special exercises for developing the abdominal muscles. (5) In very obstinate cases the patient takes, three or four times a day, a couple of tablespoonfuls of bran and as much fruit as he can eat. Fresh and stewed tomatoes are found to be especially useful. Lettuce and celery may also be used freely. The patient is allowed to take fruit between meals or whenever he feels inclined to do so. For persons suffering from hyperacidity, nonacid fruits, like bananas, pears, white cherries and melons, are used. Occasionally it is found advantageous to make the diet consist wholly of green vegetables raw and cooked, with bran or agar-agar. This regimen will usually clean off the tongue and get the bowels moving three or four times a day within four or five days. Occasionally the regimen must be continued for a week or ten days. When mechanical obstacles to bowel action, such as prolapse of the pelvic colon and adhesions or other obstructive lesions, are not present, this method will very rarely fail. (6) At first it is occasionally necessary to use an enema at 80° F. once a day. The patient should be required to go to stool on rising in the morning and after each meal. (7) In cases of colitis with a spastic condition of the descending and

pelvic colon, the colon is treated by means of hot saline enemas, and afterward there is introduced into the colon, with the patient in the knee-chest position, several ounces of a liquid culture of *Bacillus bulgaricus* and *Bacillus bifidus*, to which is added a small amount of malt sugar and boiled starch, the purpose being to change the character of the bacteria growing in the colon and thus encourage the healing of the infected mucous surface. (8) In cases in which the lower colon has lost its normal sensibility, various stimulating applications are made, among the most useful of which the electricity applied to the upper part of the rectum or pelvic colon by a bipole electrode; very weak solution of hydrogen peroxid (0.25 per cent.); solution of citric acid (from 0.25 to 0.5 per cent.), and a mixture of equal parts of carbon dioxid and pure oxygen gas (from 200 to 500 cm.). (9) In cases in which the mucous membrane is atrophied as the result of chronic proctitis, it is found very advantageous to introduce into the lower colon at night 3 or 4 ounces of a preparation of petrolatum which melts at the temperature of the body. Such a preparation may be made by melting together equal parts of liquid petrolatum and paraffin. (10) The wet girdle worn at night and a variety of other hydriatic procedures are also found highly useful in dealing with stubborn cases of constipation. Too much cannot be said in favor of bran and liquid pretrolatum used in combination. One supplies bulk, which is necessary to stimulate the sluggish colon, and the other furnishes lubrication which is required on account of loss of the normal mucus due to degeneration of the mucous membrane which results from chronic infection. Kellogg points out that except in cases in which actual and severe mechanical obstruction exists, surgery is not indicated and that the time has come to call a halt on colectomizing and short circuiting operations.

4. The Menace of Morphine to China.—Wu Lien-Teh (G. L. Tuck) states that the year 1917 will be historic as the one in which opium, the curse of China for 75 years, will be officially and finally banished from the country, for in this year the ten-year agreement made between Great Britain and China regarding its importation into China, including the last two seaports of Shanghai and Canton, will come to an end, so that even in the British Settlement of Shanghai the remaining opium shop will be closed by the month of March. The whole nation will rejoice at this happy termination of an awful vice, which once looked as if it might exterminate the Chinese race. That the drug is scarce may be ascertained by the fact that the present price in Canton is at least $15 per tael, with a tendency to rise. Except for some smuggling from Turkestan and Russia by way of Siberia very little opium will in future find its way into China, though the government and customs authorities will still have to exercise, in dealing with this enormously paying business, the greatest vigilance over unscrupulous people. Such hopes cannot be sustained with regard to morphine, for up to the end of last year all statistics point to increased importation into China. The supply of morphine comes mainly from two firms in Edinburgh and one firm in London. The declared exports of morphine from Great Britain alone in 1912 equaled 7½ tons; in 1913, 11½ tons, and in 1914, 14 tons, while in 1916 the estimate is at least 16 tons. In Japan a ton a month was imported for medicinal purposes in 1914. There is a large firm in Japan which acts as agent for the manufacturing firm in London. In 1913 alone this agent in Japan imported 2½ tons of morphine by *registered post* via Siberia. The two other British firms exported 2 tons by the same method, and 1⅜ tons came from Germany, making a total of 6¼ tons in 1913. So far it has been ascertained that neither Japan nor Germany has got the necessary plant to manufacture morphine on any large scale, and the alkaloid has come mostly from firms in Great Britain. Once arrived in Japan the morphine is usually made up into small packets or placed into small bottles, labeled in different ways—e.g., morphine, "white powder," "soothing stuff" "dreamland elixir," etc., and exported openly or smuggled secretly into China by way of Dalny, Antung, and Formosa. Almost every Japanese drug dealer or pedlar in Manchuria sells it in one form or another, and does so with impunity, because no Japanese can be arrested without complaint being first lodged at the Consulate. From these Japanese agents and subagents the drug may be passed on to disreputable Chinese who frequent the coolie depots and inject a solution, usually very dirty, with a hypodermic syringe which may be made with glass, metal, or even bamboo. Rigorous imprisonment for two years is a common sentence for Chinese found with morphine in their possession, but the principal culprits often escape punishment. Wu Lien-Teh reports that during his five years' residence in Manchuria he has seen terrible havoc wrought upon the population by this drug. Thousands of poor people die in the large cities during the winter months, partly from cold but principally from inability to work on account of their morphine habits. The evil appears to be spreading. Enormous profits are made by the dealers in this illicit trade. The profits made on 6¼ tons by the dealers in China in 1913 amounted to about $4,200,000. Unless a strong action is taken by the medical profession, as was done in the case with opium, the morphine will spread further and render futile all efforts in the direction of opium eradication. "What is to be done?" Three opium conferences have already been held at the Hague—in 1911-12, 1913, and 1914. At the second conference 44 out of 46 Powers of the world had agreed to append their signatures to the convention, and at the third conference the United States, the Netherlands, and China deposited their ratifications so as to act forthwith upon the articles of the convention to restrict the evil effects of opium, morphine, cocaine, and allied drugs. Although the representatives of Great Britain were instructed at the second conference to declare on behalf of their government their readiness to ratify, the matter has so far been delayed. The war has put a stop to many things, but not to the fact that morphine still finds its way into China. Two articles in the convention signed on January 23, 1912, states the contracting powers will enact pharmacy laws and regulations restricting the use of these drugs and their salts to medical and legitimate uses only; secondly, controlling the amount or percentage of these drugs or their salts to be used in official and non-official preparations. If proper pharmacy laws are enacted in China the problem of morphine eradication will be really an easy matter. Unlike opium it has never been declared as an article of commerce, and the Chinese Government has always regarded it as a prohibited drug. Once Great Britain refuses to sanction its export, except directly to friendly governments or legally qualified agencies, the question of smuggling will not be such a serious affair. Wu Lien-Teh offered resolutions to the Joint Medical Conference in Canton, January, 1917, as follows: (1) Drawing the attention of the government to the menace of morphine in China and the importance of taking immediate steps against its illegal use by cutting off the supply from the source. (2) Asking the government to enact without delay proper pharmacy laws to regulate the position of dispensers and pharmacists in charge of drug shops, the sale of morphine, cocaine, and other deleterious drugs and poisonous chemicals. The establishment of a central medical council would facilitate matters immensely in eradicating the trouble, and if requested the two Chinese associations (medical) would depute members to render the necessary assistance in drafting the laws for control of the condition and also for the control of the sale and use of hypodermic syringes, since no

Chinese medical man can procure a syringe for any use, and they cannot be imported into China except in the case of *duly qualified foreign medical practitioners*, foreign chemists and druggists, civil hospitals established by government in any province, military and naval surgeons, and medical colleges complying with certain conditions. This gives an opportunity for impostors to do so without punishment, while the *bona-fide* practitioners have trouble in obtaining the drugs under discussion and hypodermic syringes.

1. Status Lymphaticus from the Clinical Standpoint.—H. C. Cameron considers that the status catarrhalis has a very definite relation to that somewhat indefinite disorder of later childhood which we call rheumatism; watching many of the children from year to year he has found it impossible to avoid the conclusion that the rheumatic symptoms are added at the moment when the catarrhal nonpyogenic organisms pass the barrier of the hypertrophied lymphoid tissue and infect the blood stream. Then the child, losing suddenly his watery infantile aspect and taking on a longer and slimmer growth, is said to suffer from growing pains, Cameron sums up the situation as follows: (1) That the lymphoid overgrowth so commonly found post mortem in children is no more than an enlargement from the irritation of chronic catarrh in the corresponding mucous membranes. (2) That such children during life show evidence of faulty nutrition or infection of all epithelial structures, hair, skin, teeth, conjunctiva, and the mucous membranes of respiratory and intestinal tracts. (3) That there is usually present a characteristic wateriness of the tissues, which is dependent to some extent upon excessive carbohydrate feeding, and which is the main cause of the vulnerability to infection. (4) That local treatment of the catarrhs alone is likely to be inefficacious, and must be accompanied by a systematic attempt to achieve dehydration and improve the nutrition of the tissues. (5) That the status catarrhalis in the sense defined is a predisposing cause of rheumatism and tubercle, and carries with it a liability to sudden death at the onset of virulent infections, such as pneumococcal infections, measles, or diphtheria.

La Presse Médicale.

Azotemia in Cardiac Patients.—Josué and Parturier discuss the significance of apparent nitrogen retention in cardiac subjects. Numerous data are upon record, but it is easy to interpret erroneously. Thus with a certain degree of azotemia in asystole the exhibition of digitalis tends to reduce it. However, there is asystole without azotemia, and therefore to explain the latter a renal component should be present. But in certain investigations no such factor has been discovered and a hepatic factor has then been suggested. Naturally, with a pronounced renal lèsion the azotemia is readily understood. It is very common for asystolic patients to exhibit marked water retention, as shown by more or less edema. There is no evidence of impermeability of the kidney in these subjects and the azotemia may be accounted for by the fact that the water in the circulation cannot aid in urea elimination. It is instructive to study cases without known renal lesions, for here the two factors, cardiac and renal, do not coexist. In such cases digitalis disembarrasses the body of some of its water and the amount of N is reduced, say, from 0.7 gm. per liter to 0.4 gm., or normal. If no polyuric crisis—whether spontaneous or internal—occurs in these patients, the azotemia increases. It must be remembered that these patients are usually markedly edematous and that as a result the blood and urine are concentrated. A function of the kidney is to concentrate the blood urea, but this has already been done by the disease; hence the inactivity of the kidneys is physiological. The authors nowhere use the term N retention as equivalent to azotemia, and it is evident that the latter is purely relative. If the kidneys are damaged we also see the association of azotemia and oliguria; digitalis also reduces the degree of azotemia by causing polyuria, but cannot bring it below 0.5 gm. per liter. In other words, azotemia here is in part absolute, and means N retention. Whenever we find azotemia absent in asystole we may surmise that the liver is not equal to the work of producing the normal quantity of urea as a result of changes due to stasis.

May 17, 1917.

Ignored Hereditary Syphilis.—Sabourand recently described a new, pathognomonic dental sign of inherited syphilis, cited in an editorial note in the MEDICAL RECORD for May 19, 1917, page 861. He was promptly informed by a dentist, Drancé, that the so-called "mamillary eminence of the internal aspect of the first upper molars" is known to the odontologist as the "tubercle of Carabelli," a formation which is not known to carry any significance of a syphilitic taint. Friseau in his "Manuel du chirurgien dentiste" observes (p. 289) that "certain molars even have a fifth tubercle situated in the buccal aspect, etc." Other citations of the same tenor lead Sabourand to remark that his thesis of the syphilitic origin of these malformations is not at all compromised by these literary finds. The gifted author has made a special study of the dentition of all infants who succumb in the first, second, and third years. In many of these the teeth supply the sole evidence of the disease. During the last quarter century of his activities Alfred Fournier described many dental anomalies having this origin, and the author has been able to add to this total. Henceforth no one can undergo a general clinical examination without a complete record of the dentition. The subject with these teeth often presents a doubtful Wassermann. Aside from this fact, perhaps a fourth or third of miscellaneous cases present dental anomalies at least suggestive of possible syphilis. In conclusion Sabourand recalls his assertion that only when well developed does "Carabelli's tubercle" point to hereditary syphilis. The partially developed cases were regarded as proving nothing at all.

Treatment of Diphtheria Carriers.—Benard writes chiefly in the interest of a new insufflation devised at the Pasteur Institute, which contains dried antitoxin, new salvarsan, powdered benzoin and bismuth subcarbonate. This is used on the healthy convalescent and diseased carrier and is in no wise burdensome either to physician or patient. It is especially adapted to military requirements, for tedious segregation is done away with. Suspects can be active in the ranks if due precautions are maintained. We get the impression that war conditions have brought the subject of carrier disinfection to a head.

Journal de Médecine de Paris.

May 19, 1917.

Constipation in Soldiers.—Martinet states that constipation may be endemic in bodies of troops. The causes are self-evident—absence of fruits and vegetables from the diet and presence in the latter of substances like rice and cheese, which leave little residue; sedentary occupation, psychic inhibition, etc. This state of affairs, as far as diet is concerned, cannot be much improved There seems to be no reason for withholding dried fruits, as prunes, raisins, apples, pears, etc. Evaporated potatoes would also be of value in this connection. Bread "on the brown" containing some of the bran of wheat, or an admixture of rye or barley, would seem a logical resource; for white bread has

been ranked with alcohol and syphilis as an army plague. Agar agar is available, for it can be obtained in solid form and is readily transported. Pure cold water on rising is also a practicable resource, at least for a part of the time. A manual of gymnastics consisting chiefly of exercises while recumbent, in both prone and supine positions, for imparting vigor to the abdominal muscles is recommended. Lying on his back the subject alternately flexes the lower limbs on the trunk and the body on the thighs. In the prone position he raises himself on the hands, knees, toes, etc. Internally mineral oils are of use, especially in spastic constipation. Belladonna pills are valuable in atonic constipation. For emergencies castor oil or sodium sulphate is practicable. These four represent about all the available drugs, for others are liable to abuse and would tend to create a drug habit. The author, however, thinks a pill containing rhubarb, cascara euonymin, etc., might be a safe resource.

Dangers of Saccharine Addition to Food Articles.—A discussion of this subject took place last winter before the Therapeutic Society. Owing to the necessity of rationing sugar, saccharine is naturally suggested as a flavor, a course approved of by the government. The society would call the latter's attention to the disadvantages entailed by such a practice. In the first place, saccharine, with no food value, displaces in some dishes a nutritive article—some form of sugar—the addition of which often gives appreciable food value to substances naturally wanting in this respect, as tea. If saccharine could be regarded as a mere condiment it could have its place as a seasoning for nutritive articles, but it is a true drug with a physiological action unfavorable to the human organism, in that it is able to antagonize the action of the digestive enzymes and thus retard digestion. It has been shown to inhibit digestive hydrolysis, especially in the stomach. Its presence in dentifrices has even been made the subject of a crusade. The saccharine addition is for both antiseptic quality and flavor, but prolonged exposure of the teeth to this substance is pronounced injurious. It is true that Germany sanctioned the dietetic use of saccharine, but we have no means of knowing how the Germans feel about it today. At present saccharine is accused of causing hemorrhage of the stomach in the absence of other known factors.

Le Progrès Médical.

May 19, 1917.

War Bread and Maize.—Weill and Mouriquand publish the results of some experiments on the practicability of maize as the chief constituent of bread and the possible relations between maize diet and pellagra. The authors had already shown that decorticated cereal grains and legume when fed to pigeons and fowls as exclusive diet lead to paraplegia and death. The cause of the latter is believed to be the depreciation of a ferment contained in the cortex of the grains, which is as essential to nutrition as sufficient calories, protein, and mineral matter. The authors fed whole maize to a pigeon aged 6 months as sole diet for a period of 240 days. The bird, shut up in its cage, showed great activity and vigor, was in perpetual motion, pecked at its bars and seemed "mad." Control pigeons living exclusively on entire wheat, barley, rice and oat grains were well nourished and vigorous, but showed no such exalted state as the maize-fed bird. The ration of the control birds was cut down to one-sixth or one-seventh, until death occurred from inanition; no beri beri syndrome appeared at any time. This held good of all the grains, but not in the same degree. Rice seemed by far the best value for prolonged survival (80 days as against 31 for wheat, 29 for barley, etc.). The maize-fed bird was now tested and survived 88 days. When a mixture of whole grains was heat sterilized (120° C.) the birds survived 90 days and died paralyzed, but a certain addition of raw grains prevented beriberiism. One-third part of raw grains appeared to give perfect protection. Pigeons were now fed on decorticated, highly-milled maize. The latter was refused and the birds were artificially crammed with it. After a period of sluggishness flight became impossible (33rd day) and death preceded by paralysis soon followed. Emaciation had also taken place. There were changes in the femoral epiphyses and adrenals. Hence, both cooking and decortication deprive the grains of vitamines or ferments. In regard to pellagra we know that recently it has been seen in association with scurvy after maize flour diet. The zeïsm or maize intoxication of Rhodesia appears identical with pellagra. In Belgian Congo beri beri patients showed also a pellagrous syndrome. This association of three deficiency diseases in subjects fed on highly-milled maize cannot be a mere coincidence, but the interrelations of the three are very puzzling. Pellagra is in part a skin dystrophy, perhaps analogous to the shedding of the feathers of fowls with beri beri.

Ratbite Fever. — Laroche and Durozoy described a case of ratbite disease in France. The man was bitten on the wrist. Three weeks later there developed a large nodule as large as a silver dollar, accompanied by lymphangitis, and epitrochlear and submaxillary adenopathy.—*La Presse Médicale.*

Dysenteric Esophagitis.—Ameuille and Périn in the course of an epidemic of bacillary dysentery found two patients with a form of dysphagia so severe as to suggest hydrophobia. Both cases ended fatally and autopsy showed very elongated ulcerations suggesting the ulcers of dysentery.—*Le Progrès Médical.*

Areflexia in a Subject with Head Wound.—Souques relates the case of a soldier wounded in the head by a fragment of shell in which a meningitic syndrome developed. Total areflexion developed, due apparently to compression of the nerve roots or to neuritis of the same.—*La Presse Médicale.*

Treatment and Cure of Myopia.—Bacchi in order to cure myopia advocates progressive pressure on the eyeball in the anteroposterior direction by means of the apparatus of Roger d'Ansan. The value of this procedure is often very convincing and the author has demonstrated cases before the Academy of Medicine.—*La Presse Médicale.*

Wassermann Reaction and Medication.—Picado discovered that intravenous injections of collargol could affect the blood Wassermann test in either direction, intensifying (reactivation), or inhibiting. He believes that it should not be made when the patient is under the influence of any form of medication whatever.—*Le Progrès Médical.*

Twenty-four Chancres in One Subject.—Butte and Simon saw a subject with multiple chancres, some of which were seated on the glans and in the sulcus, while others in close juxtaposition formed a sort of mosaic on the pubes. All appeared simultaneously.—*Le Progrès Médical.*

A New Microbean Cause of Rheumatism.—Chantemesse and others have isolated and cultivated a hitherto undescribed microorganism which can set up in mankind articular rheumatism. The source is not mentioned. In animals it has caused arthritis and endocarditis. The new organism is a socalled mycobacillus, intermediate between the bacilli and moulds.—*La Presse Médicale.*

Progress in Our Knowledge of Alkaptonuria.—In a recently published monograph on this affection by Söderbergh two new facts are given prominence. First a positive Wassermann may be present, not due to associated syphilis or other known cause. Second, the underlying condition may be expressed as a special form of osteitis deformans. — *Correspondenz-Blatt für Schweizer Aerzte.*

Graves' Disease in Italy.—In reply to a question by "Subscriber No. 5071" in reference to the treatment of this affection, the editor—who terms the affection in question the Basedow-Flaiani disease—prescribes country life with prohibition of coffee, tea, tobacco, and alcohol. Much emphasis is placed on stable galvanization of the sympathetic. Bromide and digitalis or strophanthus are useful. Surgery is the last resort.—*Il Policlinico.*

Production of Phenol by Microorganisms.—Berthelot looks forward to the discovery in the human intestinal flora of a bacillus which secretes phenol in relatively large quantities—tenfold that of known phenol producers. With thyrosine as sole nutrient medium it may furnish in a fortnight at 37° C. 800 mg. of phenol per liter.—*La Presse Médicale.*

Book Reviews.

BOTANIC DRUGS: THEIR MATERIA MEDICA, PHARMACOLOGY AND THERAPEUTICS. By THOMAS S. BLAIR, M.D., Editor Medical Council; Author of "Public Hygiene," "A Practitioner's Handbook of Materia Medica and Therapeutics," and "Pocket Therapeutics"; formerly Neurologist to Harrisburg (Pa.) Hospital. Price, $2.00. Cincinnati: Therapeutic Digest Pub. Co., 1917.

BY the cutting off of German products, all countries have been deprived to a great extent of the synthetic medicaments. A great many physicians do not regard this deprivation as an altogether unmixed evil. In the first instance, it will spur the chemists of other countries than Germany to manufacture synthetic remedies, and it may also show how excellently the sick can get on without some of them.

Old-fashioned drugs, and especially plant drugs, have been almost wholly neglected since the introduction and huge development of the manufacture of medicaments by synthetic methods, so much so, indeed, that physicians of today know little about them. In this book Blair has presented in concise form a convincing argument for the restudy and enlarged use of galenicals. The work is peculiarly apropos and moreover it would seem to be the duty of the medical profession to study galenicals scientifically. The author has written a thoroughly practical and reliable work on the subject and one that may be utilized by the practitioner with great advantage to the patients and himself.

THE OFFENDER AND HIS RELATIONS TO LAW AND SOCIETY. By BURDETTE G. LEWIS, A.B., Commissioner of Correction, City of New York. Illustrated. Price, $2.00 net. New York and London: Harper and Brothers. 1917.

THIS work, as its title denotes, deals with the relationship of the offender to law and society. It is written by a man who is intimately acquainted with his subjects, an acquaintance gained by a special *inherent aptitude* for this branch of study, developed and sharpened by experience, and discusses the matter in all its complicated phases. The book may be highly recommended to all those who have the interests of their fellow creatures close at heart. Most of the work is of particular concern to the medical profession.

DISEASES OF THE GENITO-URINARY ORGANS AND THE KIDNEY. By ROBERT HOLMES GREENE, A.M., M.D., Professor of Genito-Urinary Surgery, Medical Department of Fordham University; Genito-Urinary Surgeon to the City and to the French Hospital, New York City; Fellow of the American Association of Genito-Urinary Surgeons; and HARLOW BROOKS, M.D., Professor of Clinical Medicine, University and Bellevue Hospital Medical School; Visiting Physician to the City Hospital and to the Montefiore Home for Chronic Invalids, New York City; Consulting Pathologist to the Muhlenberg Hospital, Plainfield, and to the Hackensack Hospital, N. J.; Consulting Physician to the Beth Israel and to the Union Hospitals, New York; to the St. Mary's Hospital, Hoboken; to the Greenwich Hospital, and to the New London Memorial Hospital, Conn. Fourth Edition, thoroughly revised. Price, $5.50 net. Philadelphia and London: W. B. Saunders Company, 1917.

ALTHOUGH the major portion of this edition is unchanged from the previous issue, yet sufficiently necessary additions and revisions have been made to modernize the work. Notable among the added matter are new chapters or sections on the value of the *x*-ray in urological diagnosis, tests showing the degree of kidney permeability, anesthesia in urology with full description of Heinrich Braun's method of conduction anesthesia with its modifications, syphilis of the bladder, and elephantiasis of the scrotum. The less important additions and revisions are, reference to the Mendelian principles of heredity in the consideration of tumors of the urogenital tract, the description of modern instruments such as the Goldschmidt urethroscope, the diathermic high frequency apparatus for fulguration, and the complement fixation test in gonorrhea. The test dealing with renal lesions has been modernized by giving due attention and consideration to the recent advances in the determination of retained nitrogen blood content. The authors take a very practicable viewpoint when they write: "While there can be no question whatever but that much is yet to be learned from close study by nitrogen partition methods, we are of the opinion that for clinical purposes, and taking into consideration the time and expense necessary for the more elaborate determinations, the simple determination of the total retained filterable nitrogen is quite sufficient." In the discussion of uremia the authors believe the prognosis to be grave when the systolic pressure is low, the diastolic pressure high with a resulting low pulse pressure. Other additions obtrude themselves upon the reviewer because of their absence in contemporaneous works. For example, in the paragraph on the seminal fluid we are cautioned to bear in mind that even though visibly viable spermatozoa are present, ability to impregnate does not follow since certain serum affinities must also be present for the phenomenon. A curious fact, noted in general considerations of tumors of the urinary system, is that a large number of chemical examinations of many urines from patients suffering from cancer showed all to contain a large increase in the amount of neutral sulphur. In general this fourth edition is complete, well balanced and judiciously illustrated.

LA PROTHÈSE DES AMPUTÉS EN CHIRURGIE DE GUERRE. Par A. BROCA et DUCROQUET. Collection Horizon. Prix, 4 francs. Paris: Masson et Cie., 1917.

THIS little work comprises 208 text figures. The accompanying text is not extensive. In the publishers' notice it is stated that the prosthetic apparatus is "more or less American" in origin. The socalled "American nose" a socket for the reception of numerous workmen's tools competes with the old vice system. There is a radical distinction between the artificial hand for general usage—in eating, dressing, etc.—and the special artisan's prosthesis which varies largely with his calling. Such prosthesis is available for gardeners, wine growers, packers, plumbers, leather workers, brush makers, carpenters, chauffeurs, motormen, etc. In addition to "terminal tools" workers who have undergone amputation above the elbow have an extension arm and elbow which serves equally for both kinds of terminal prosthesis.

HYSTÉRIE-PITHIATISME ET TROUBLES NERVEUX D'ORDRE REFLEXE EN NEUROLOGIE DE GUERRE. Par J. BABINSKI ET J. FROMENT. Collection Horizon. Prix, 4 francs. Paris: Masson et Cie., 1917.

ANY work by Babinski, perhaps the logical successor of Charcot in French neurology, should be well worthy of study. The present volume is virtually three monographs in one, of which the first deals with hysteria, the second with reflex disorders and the third with the association phenomenon. Babinski, who coined the word "pithiatism," uses it here as a synonym for hysteria. Literally it means "curable by suggestion." However happy the conception of the term, it has never come into general use, so that the author retains the term hysteria in the title of the work. The volume is a rich one, the 267 pages of text comprising an extensive bibliography. Eight photographed plates represent numerous separate pictures, and these with 37 text figures illustrate the text quite liberally.

THE SURGICAL CLINICS OF CHICAGO. April, 1917. Volume I, Number 2. Published bi-monthly. Price, $10.00 per year. Philadelphia and London: W. B. Saunders Company.

THIS number of the Chicago Surgical Clinics contains presentations of cases from fifteen clinics, some thirty-five cases in all, in about two hundred and twenty pages, including numerous illustrations. It goes without saying that the presentations for the most part are very brief. It is very interesting to see how extensive is the use which is being made of blood transfusion, especially as a prophylactic measure. Of particular interest are the clinics on pernicious anemia and congenital dislocation of the hip. A number of interesting cases are described in this number and many details of operative technique presented in concise and clear fashion.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 27, 1917.

DR. GEORGE W. KOSMAK IN THE CHAIR.

Attempted Abortion in the Absence of Uterine Pregnancy.—Dr. ARTHUR STEIN reported this case. He stated that in view of the steadily increasing number of criminal abortions all over the civilized world it was probable that not only was attempted abortion in the absence of pregnancy not as rare as was sometimes supposed, but that it was of considerable gynecological importance on account of the associated dangers which were even greater than those of criminal abortion where pregnancy actually existed. In studying this subject it was advisable to make a distinction between the following two groups of cases: (1) Cases of attempted abortion in which the uterus was empty and pregnancy did not exist. (2) Cases of attempted abortion in which the uterus was empty but in which there existed an ectopic pregnancy. The very high mortality which according to recent investigations was about 43 per cent. was explained by the reckless repetition of the disappointed woman's futile efforts to interrupt a fancied pregnancy. In those women who were already endangered by the existence of an ectopic pregnancy the sequelæ of attempted abortion were likely to prove especially serious if not actually fatal. The following case illustrating the dangerous character of attempts to induce the premature expulsion of the ovum in an erroneously assumed pregnancy came under the writer's personal observation at the Harlem Hospital, in Dr. Brodhead's service The patient was 43 years of age, a V-para, who attributed a six weeks' retardation of the menstrual flow to pregnancy which she had attempted to arrest by the introduction of an alum stick into the uterus. This was followed by a chill lasting an hour and then by fever. There was persistent vomiting for a day with general malaise. The patient complained of hypogastric pains. A considerable amount of bloody discharge was passed from the vagina. When first seen, three days after the attempted abortion, the patient was in a serious condition. A diagnosis of infected, incomplete abortion was made and the uterus was curetted under all necessary precautions. A small amount of tissue with a fetid odor was removed. At night following the curettage, the patient's temperature rose to 105.6° F., and three days later she died of general septic peritonitis. Post-mortem examination showed no signs of an existing pregnancy, either macroscopically or microscopically.

Dystocia Due to Large Fibroid of Cervix: Craniotomy—Exhibition of Specimen.—Dr. STEIN reported this case. He stated that the patient, a woman 37 years of age, a primipara, was sent to the Harlem Hospital on January 28, 1917, with the history of having been in labor over 72 hours, the amniotic sac having broken on January 25. The patient had felt no life for twelve hours. High forceps had failed to engage the occiput and the patient had been given two doses of pituitrin of one c.c. each at hourly intervals without inducing strong contractions. At the time of her admission to the hospital she was partly unconscious owing to the fact that she had been under narcosis for several hours previous to her admission. Her pelvic measurements were normal. There was marked edema of both legs and the outer genitals, especially of the labia majora. On inspection a large tear of the perineum was seen, involving the sphincter and reaching into the rectum. The uterus was tetanically contracted, apparently due to the injections of pituitrin. A typical Bandyl's ring was visible. The uterus was found to be lying over toward the right side of the abdomen. No fetal heart sounds could be heard; owing to the tetanic contractions of the uterus no exact diagnosis of the child's position could be made. The head was felt firmly engaged in the brim of the pelvis. In view of the conditions described, perforation of the head and extraction of the child was decided upon. Upon attempt to extract the child, in spite of the application of all kinds of appliances, regular forceps, basiotribe, etc., it was found impossible to move the head as much as one-half an inch. After continuing efforts unsuccessfully for about an hour after perforation Dr. Stein was called to see the patient. An effort to introduce the hand into the uterus and perform version failed utterly due to the tetanic contraction of the uterus. That also was one reason why embryotomy was not performed. Because of the unavailing efforts to extract the child a diagnosis of a large monster or a tumor of the pelvis was made. In view of the many vaginal and intrauterine manipulations that had been resorted to, an abdominal cesarean section was not regarded as the correct procedure in this case. Further attempts to extract the child through the vagina were made which at the end of forty-five minutes were successful. A Simpson forceps, after severe traction and pressure from above, brought the crushed head out of the vulva. At the same time hooks were placed in the axilla and the child was with great difficulty extracted. The child without the brain weighed 7 pounds 5 ounces. The placenta was quickly expressed and a rapid suture of the total laceration of the perineum performed. The uterus was packed. A large tumor was then found to be lying in the right side of the pelvis extending into the larger pelvis where it could easily be felt. The patient was placed in bed, stimulated, and infused with saline solution. In spite of all treatment she died from shock four hours after confinement. The specimen consisted of the puerperal uterus. Attached to the right and posterior side of the cervix there was an extremely hard myoma, 6 by 4 by 3 inches in dimension. The myoma was very hard, firmly attached to the uterus, and had developed upward in between the two layers of the broad ligament.

Dr. GEORGE L. BRODHEAD said he had seen patients of the type reported by Dr. Stein who, not knowing whether they were pregnant or not, decided to take no chances and attempted to produce abortion. At the Harlem Hospital they saw many of these septic abortions and had had a few in women who were not pregnant. The second case presented by Dr. Stein was interesting not only in itself, but also in that it brought out the importance of antepartum diagnosis. If this patient had been thoroughly examined before she went into labor the existence of the tumor might have been revealed and a cesarean section performed. It also illustrated how one might lose a living infant by delay in making an accurate diagnosis. When the conditions were present as Dr. Stein first saw them the problem was merely how to get the child out with the least trauma to the mother.

Dr. ASA B. DAVIS said that some eighteen or twenty years ago a patient came under his care for a short time who gave a history of several previously induced abortions brought on by passing a sound into the uterus. This time this plan had been repeated for several days. He did not examine the patient but sent her to the Lying-in Hospital. The patient was curetted. Evidence of abdominal hemorrhage was found; upon opening the abdomen a ruptured ectopic pregnancy was revealed. The operation was completed as well and as expeditiously as possible. The patient died within forty-eight hours of sepsis, hemorrhage, and shock.

Dr. HIRAM N. VINEBERG said he had seen so many cases of ectopic pregnancy in which abortion had been attempted that he once made the statement that these cases might have been made ectopic by the passage of sounds at a very early stage of conception. It seemed possible that this theory might be correct and that the passage of the sound might have something to do with the passage of the impregnated ovum through the tube. None of the cases of this kind that he could recall had become septic and all as far as he could remember recovered after operation.

Rupture of the Fetal Liver During Breech Extraction.—Dr. GEORGE L. BRODHEAD reported the case of a primipara, 26 years old, with a normal pelvis, and with a child presenting by the breech. The cervix became fully dilated and the breech descended, but as the fetal heart was increasing in rate and as the mother's pulse was more rapid and she was becoming exhausted, extraction was performed. The legs were fully extended and were brought down with considerable difficulty. There was a double nuchal hitch and in the endeavor to extract the arms, the child's body was rotated in both directions

several times. The arms were extracted and the head came out easily. The infant weighed 8 10/16 lbs. and soon cried vigorously. Until a few hours before the child's death, on the third day, its color was good, it nursed well, and seemed to be doing nicely. Then the breathing became shallow, the child became very pale, and death ensued. The autopsy revealed free blood and clots in the peritoneal cavity: there was a rupture of the upper lobe of the liver just under the diaphragm, the capsule being ruptured over an area as large as a half dollar, about ¼ inch of the liver tissue being torn away. With such an extensive laceration and with so much bleeding, it was remarkable that the child was apparently so well for the three days following birth. They were all of the opinion that in all probability the rupture occurred during the manipulation of the body which was necessary in order to extract the arms, but no undue force was used. The trauma in their experience was unique and the case was reported for its rare interest.

Traumatic Injury to Fetal Liver During Breech Extraction.—Dr. GEORGE L. BRODHEAD reported the case of a primipara, at full term, aged 25. She had been in labor 29 hours. The pelvic measurements were normal, the position was R. S. A. and the os was fully dilated. As the pains were few and not strong, the child was extracted. The legs were extended, and brought down, and the extraction was comparatively easy. The child nursed properly and acted like a healthy infant up to within a half-hour of the time of death. There were no signs of hemophilia. About an hour after the last nursing the child became very pale and died within a half-hour. The autopsy was performed by Dr. C. S. Cassasa who gave the following report: The skin and mucous membrane of the lips very pale. Rigor mortis was very complete. Post-mortem hypostasis was scant. The lungs were serated throughout. The left ventricle was contracted. The heart's blood was very scant and fluid. The umbilical cord was normal. The abdomen contained about six ounces of fluid and clotted blood. The entire renal impression of the liver was occupied by fluid blood, the location of which was between the liver substance and the capsule. Examination of the capsule over this area showed a circular defect about one-sixteenth of an inch in diameter. Gentle pressure over this collection of blood caused an escape through the defect. A sagittal section was made through the diaphragm and liver. At the junction of the posterior layer of the coronary ligament to the liver, clotted blood and lacerated liver tissue were found. The laceration extended ½ inch in the direction of the ligament, its depth being about 1/32 inch. The other organs were normal. One of the interesting features in this case, as in the preceding, was that the child lived three days with apparently no symptoms, and then suddenly died.

Dr. HIRAM N. VINEBERG recalled an instance of rupture of the liver in an infant. In this case the delivery was normal, and the baby was otherwise normal. It died three days after birth and at autopsy a large hemorrhage from the liver was found. In this instance the hemorrhage was certainly not due to hemophilia, as there was no such history in the family and the woman had previously given birth to perfectly normal children.

Dr. GEORGE W. KOSMAK said that if they could get more autopsies they would probably find that these cases occurred more frequently than they had thought. He recalled an instance in his private practice in which the baby died suddenly and Dr. Losee performed the autopsy. He found a large hemorrhage into the abdominal cavity. In this instance the delivery had been precipitate and the baby born in the bag of membrane. Dr. Losee attributed the hemorrhage in this case to asphyxia, and his theory seemed plausible. In reference to breech extractions, in view of the frequency with which the arms of the child were extended, a safe rule to follow was to deliver the arms as soon as the tip of the scapula was born. In that way a good deal of trauma might be saved.

Full-Term Abdominal Pregnancy with Macerated Fetus: Streptococcus Infection of the Sac and of the Uterus.—Dr. ASA B. DAVIS reported this case. The patient was 34 years old, gave a good family history, and had never had a severe illness, nor any operation. She was married in 1900, and her first child was born in March, 1902, after a normal pregnancy. Six years ago she was treated with tampons for what was said to have been "falling of the womb." She denied any contraceptive methods. Since the beginning of the present pregnancy there had been a rusty mucus discharge at intervals of a week or ten days and especially at what should have been the dates of menstruation. Full term delivery was expected about January 1, 1917. Fetal life was felt from October, 1916, until January, 1917, but none after this date. After the first three months of pregnancy there was no nausea or vomiting until January 22, 1917, when she had three attacks, and again January 26, 1917, when she had two attacks; she then had also an attack of faintness with partial loss of consciousness which continued about fifteen minutes. A sense of unusual pressure in the abdomen had been noticed for the past two weeks. On January 25, the temperature was 100.2° F., pulse 110, and respirations 28. In the late afternoon of January 26 more distensions of the upper part of the abdomen was observed. On January 27 the temperature was 101.4° F., pulse 140, and respirations 32. The blood pressure was 130. The blood examination showed red cells 3,810,000, hemoglobin 68 per cent., color index 0.6, leucocytes 21,200, polymorphonutrophiles 91. The diagnosis rested between a uterine pregnancy past full term with gas bacillus decomposition, or an abdominal over-due pregnancy with a like decomposition of the fetus. Against the first theory was the fact that no membrane could be felt in the uterus; gas contained under such great pressure should have bulged the membranes downward, so that they could have been felt readily at the internal os or lower. The uterus was curetted. The cavity was roomy and crowded well over into the left iliac fossa. It was empty save for a considerable amount of grumous material, old clots, and fibrin mixed with clots. It had the macroscopial appearance of material removed in a case of incomplete abortion of rather long standing. The uterine wall was soft and the curette did not readily come down upon firm muscle. The abdomen was opened and no intestines or omentum came into view at any time. An ovoid mass, dark, dirty green in color, filling the whole abdomen and adherent to the abdominal wall presented. The wall of this mass appeared to be of considerable thickness and under great tension. During the separation of the abdominal wall from the mass on the left side there was a sudden hissing report, quite loud and similar to those familiar to the automobilist. It was then found that the sac was ruptured at its upper mid-portion anteriorly and a large quantity of dark, thin, foul smelling fluid was escaping. Cultures were taken and, before and after this happened, the laboratory reported *Streptococcus viridans*. No gas bacilli were found. The opening in this sac was enlarged and a well-formed female fetus was found with breech above and to the right, dorsum right, curled down to the left with vertex left and below at the site where ballottement had been found prior to the operation. The fetus was not much decomposed. It was removed and the placenta was found spread out over the lower and right portion of the cavity, adherent to the cecum and neighboring intestinal and abdominal wall. The entire wall of this cavity was of a dark, dirty greenish color. This was probably an early tubal abortion. A history of sterility over a considerable time was quite apt to be found in cases of ectopic pregnancy. At this time, March 7, the patient's blood count showed 2,940,000 red cells, hemoglobin 58 per cent., leucocytes 17,200, polymorphonuclear 75 per cent. An early recovery was now looked for, though it was possible that an abdominal hernia might develop which could be readily dealt with. Had the sac and placenta been removed at the time of the operation, it was probable that the patient would not have survived more than a few hours.

Dr. VINEBERG said he had an experience of this kind in a woman who had gone to full term and beyond. She had been under observation in a hospital of this city for several days where a diagnosis of inoperable malignant growth had been made. A month later she came under his observation. With the history given and the physical signs it was not difficult to make a correct diagnosis. At operation the placenta was found adherent to the abdominal wall and the hemorrhage was

very profuse. By working rapidly he had succeeded in ligating the main blood vessels and controling it. He then removed the entire placenta, but the membranes were inclusively adherent and these he sutured into the parietal peritoneum and packed the cavity with iodoform gauze. The fetus, weighing over nine pounds, was dead. The patient made a satisfactory recovery.

Dr. A. J. Rongy said that Dr. Davis' case recalled an interesting case that came under his observation recently. This woman was about 25 years of age; married four years, and had been operated on for ectopic pregnancy by him about two and one-half years ago. Eight months later she returned, being about three months pregnant. Examination at this time and about three months later showed her condition to be normal. In the seventh month she had a severe attack of sharp pain in the abdomen. A neighboring physician was called and administered a hypodermic of morphine. The following day she felt better, but felt no fetal movements. During the eighth month she consulted the speaker with reference to her condition. On examination she presented a clinical picture of a woman who was in the eighth month of pregnancy; she suffered no pain or tenderness anywhere. He informed her that the fetus was most likely dead and that she should wait ten to fourteen days, and if labor did not set in it should be induced. As labor did not ensue at the expiration of this period, she was admitted to Lebanon Hospital for the induction of labor. The usual procedures for the induction of labor failed of success, and as he did not wish to perform a major operation at that time the patient was sent home and told to return to the hospital as soon as labor pains set in. She was readmitted to the hospital after being convinced that labor would not set in of its own accord. At this time he had informed the family that the fetus might have escaped into the abdominal cavity at the time she suffered the attack of pain in the seventh month. In order to reassure himself, however, he examined the patient under anesthesia. On attempting to dilate the cervix a great deal of bleeding was encountered. The cervix was packed and the patient returned to bed. Two days later, on opening the abdomen, a large amount of fluid escaped and a fully developed fetus weighing about six pounds was found floating in the abdominal cavity. The placenta, hard, dry, pale, and shriveled, was found to be attached in the region of the right kidney. There was no evidence of fetal membranes. The abdomen was closed and the wound drained at its lower angle. The patient made an uneventful recovery. Dr. Rongy said that at the present time he would not enter into a discussion as to whether this condition was primarily a tubal abortion with a subsequent abdominal pregnancy or a rupture of the uterus during the seventh month of pregnancy and the escape of the fetus and the placenta into the abdominal cavity, though he was inclined to the latter view.

Dr. Brodhead said they had had one case of abdominal pregnancy in the hospital that died without a diagnosis having been made. At autopsy an extrauterine pregnancy was found. A case of which he had heard recently showed the difficulty of making a diagnosis in some cases. This patient gave a history of having gone through a normal pregnancy. She went beyond full term and attempt was made to induce labor. The obstetrician tried to introduce de Ribas bags, but could not do so successfully, and it was decided to perform an abdominal section. On opening the abdomen they found what appeared to be an ovarian cyst. It was easily separated from the surrounding viscera, the vessels tied off, and the specimen laid aside as an ovarian cyst. Later someone opened the specimen and found a seven and one-half macerated fetus. That woman was examined by a number of experienced obstetricians and not one had made the correct diagnosis until the sac was opened.

Dr. Vineberg said that in abdominal pregnancy the uterus enlarged to a size corresponding to that of a uterine pregnancy at about the fourth month.

Dr. George W. Kosmak stated that Dr. Cragin had reported another one of these unusual cases of abdominal pregnancy in a recent number of the *American Journal of Obstetrics*.

Dr. Davis said that within the past five or six years he had seen three other full term or over abdominal pregnancies operated upon by other surgeons in the Lying-in Hospital. The first two mothers recovered, and he believed one child. In the third case the child was dead before operation and the mother died shortly after from shock. In all three cases the entire sac and placenta were removed at the time of operation and the abdomen closed. He did not remember whether drainage was used. Apparently none of these cases were infected. Some ten years ago Dr. Davis said he had removed a five-months' abdominal pregnancy with sac and placenta intact, closed the wound, and the mother recovered without event. Local abdominal tenderness under pressure was a rather constant symptom in abdominal pregnancy.

General Observations upon Antenatal Pathology.—Dr. Edward A. Schumann of Philadelphia read this paper. He said that observation, speculation, and study of monstrous infants and of gross developmental errors had occupied the minds of men from the time of the beginning of recorded facts, but until recently the observation had been cursory, the study negligible, and the speculation an absurd mixture of medieval superstition of biological falsehood. Even now the great subject of antenatal pathology was assumed as being entirely contained within the confines of teratology, a grievous error. It must be remembered that the child was by no means a little man, that physiological processes, both normal and pathological, differed greatly in the infant and the adult and that the manifestations of disease varied within wide limits in the developmental and mature epochs of life. It was the grouped study of certain phenomena and occurrences of prenatal and intranatal life, their effect upon the individual, their relation to other departments of biology, medicine, and sociology, that truly constituted antenatal pathology. Examples of the close interdependence of antenatal pathology to postnatal conditions might be multiplied indefinitely. Suffice it to say that its ramifications extended into every department of medicine to a greater or less extent. Antenatal life was so intensive, and was made up of so many almost conflicting factors, that for a proper understanding of its biology it must be divided and subdivided into periods which would correspond with the particular character of the phenomena occurring during these divisions of time. Ballantyne's description of antenatal physiology was scarcely to be improved upon. Disease in the fetal period was comparable to postnatal disease with the modifying factors of the nature of the fetal environment and the influence of the placental circulation. Classification of fetal disease was a complex task, and even the most condensed grouping covered practically the whole subject of medicine. Ballantyne's plan was the one which seemed to be most satisfactory and complete. Syphilis stood out among the transmitted diseases as of special interest. The prevalent idea that syphilis was a frequent cause of early abortion seemed to be disproved, it being found that in most cases the fetus was infected in the latter months of pregnancy, when it might die and be prematurely expelled, might be born alive and show signs of an active infection, or might show no signs of syphilis until some months after birth. The mode of infection was now thought by common consent to be through the maternal blood stream, unless possibly there might be a granular "resting stage" in the life cycle of the *Treponema pallidum*, at which time the granules might pass into the semen. The treponema itself had not been demonstrated in seminal fluid. It was known that certain toxicological conditions of the mother might in some wise be transmitted to the fetus, but here their knowledge was vague and largely based on inference. Alcoholism in the mother, if at all continuous, did certainly have a deleterious effect upon the developing fetus, but the mechanism of its action was not clear. Such intoxications, together with the various chronic metallic poisons, as lead or phosphorus, caused fetal disease, not by a direct action, but by producing a toxic effect upon the ovum or the spermatozoon they predisposed to morbid embryonic states, which, in turn, caused fetal disease. Imbecility, epilepsy, and certain chronic organic degenerations seemed to follow these poisonings. The idiopathic diseases of the fetus might be defined as all these definitive lesions whose cause

was not known. The term idiopathic was at best a poor one and as used in the classification merely grouped the conditions of unknown origin. General edema of the fetus, for example, had been the subject of considerable research. He said he had already expressed it as his opinion that the disease was primarily of placental origin, an end result of maternal toxemia. The remaining groups of fetal disease were largely explained by their names, and to discuss them would lead to a review of practically the whole subject of clinical medicine. They were mentioned simply as an illustration of the enormous field covered by fetal pathology. The injuries and accidents of birth and the irregularities of beginning function in those organs, latent during intrauterine existence but essential to life immediately upon the cessation of placental circulation, constituted the pathology of the intra- and neonatal period. It had been well said that "birth is the traumatic transition from an intrauterine to an extrauterine existence." There now remained for discussion what was really the crux of the entire matter—What practical application were they, as obstetricians, to make of the mass of vague theories, abstract principles and nosological facts contained in a study of antenatal pathology? Their concern was to better the standards of the community, the race, and the species, not so much by an improvement of what they called the normal type (though that was an ideal to be striven for) as to decrease the number of imperfect individuals born, and to lessen in each case the individual imperfection to an irreducible minimum. This was to be done by approaching the subject from several angles. First, an analysis of the history of the parents in much more detail than was the common practice. It was astonishing what a wealth of data, some of it of enormous importance, might be obtained, first by a searching amnesis, and, second, by encouraging the establishment and maintenance of a family record of physical events. First, then, a more careful investigation as to the probability of transmitted abnormalities. Second, more careful study of the obstetric patient from the standpoint of the child. It was routine practice to examine the mother for evidence of organic disease, to determine her pelvic size and contour, to investigate the character of the urine, the blood pressure and the like, but it was unusual for periodic examination of the fetus to be made with regard to the uniformity of growth, the nature of the movements, evidences of faulty circulation, or of interference with nutrition from any cause. Fetal disease was often associated with pain or discomfort on the part of the mother, and investigation of such condition should be made with a view to the possible diagnosis of the cause of the symptoms, not only with reference to the mother, but also to the child. The diagnosis of antenatal disease was still almost virgin ground, the more so by reason of the dearth of detailed observation of the pregnant woman who eventually gave birth to a diseased infant. Certain physical signs had been orientated, however, and formed a nucleus which might develop into a considerable group of diagnostic facts. Hydramnion, for example, might be diagnosticated, and was known to be very frequently associated with monstrous infants or with twins. It was known that weak, irregular, and arrhythmic fetal heart sounds might be present in the case of anencephalic or other monsters in which the cerebral and spinal centers were so ill developed that this regulating action on the heart muscle was lost. A positive Wassermann reaction in a pregnant woman would prove beyond question that her child would be infected with syphilis. The fetal size and state of nutrition might be estimated, the vigor and character of the fetal movements had been found to hold certain significance, and, in fact, the physical signs leading to a diagnosis of fetal disease, if marshaled in order, already formed a respectable group, and with a quickening interest in antenatal diagnosis, must grow to become an important factor in obstetric work. The future offered hope, and it seemed to him beyond question true that more careful study of the pregnant woman from the standpoint of the child, her treatment and observation, not only as an outpatient, but in hospital, whenever there was any reason to suspect any fetal difficulty, a collection of detailed data upon the course of all pregnancies which differed in any way from the normal, and their results as regards the infant, would enable them to shortly have many more facts at their command, and that by the application of their knowledge of the results of abnormal pregnancies to the causes of disease the whole subject of antenatal pathology would attain to a state of workable scientific information, giving to medicine another unit of power for the betterment of their race and species.

Dr. J. R. Losee, after congratulating Dr. Schumann on the completeness of his paper, said we saw many abnormalities of excess and defect, which had been grouped under embryological pathology. This branch of antenatal pathology was being carefully studied by Dr. F. P. Mall of Johns Hopkins. The various observers had all carefully described the anomalies and had made complete histories, but the reason why certain parts did not completely develop had been explained by many different and opposing theories. The pathology of the late fetal period was practically the same as that of the post-natal period, for the disease had been transmitted from the maternal organism in most instances. Syphilis was a well known cause of premature labor and in 40 to 50 per cent. of the cases of syphilis the fetus was dead. How could the remaining 50 per cent. of still-births be explained? It seemed to him that in some instances there was a mechanical cause, or some pathological condition of the decidua, which prevented the placenta from remaining attached to it. Such diseases as fetal anasarca, ascites, and the many congenital bone conditions all awaited a satisfactory explanation as to their cause.

Dr. Samuel Bandler said that if this paper was to be of real value to them or to the advancement of the science of eugenics they must not be satisfied with what they learned from the minute pathology of disease, but they must look at the gross facts and see what they could teach them. If this paper meant only that the embryo had certain defects and told us only why we had an embryonic monster its value would be limited. But syphilis had been mentioned, and alcoholism had been mentioned, and heredity had been mentioned, and they had been told of the importance of getting a family history. That did not mean a history of cleft palate or webbed feet merely and the passing by of the important things. In the science of eugenics one wanted to know not simply whether the parents were syphilitic or alcoholic, but one wanted to know the family tree for several generations, and one wanted to ascertain a great many facts. To know whether the parents had had hypothyroidism, Basedow's disease, or myxedema were all important things which should be considered. Hereditary syphilis was said to be important, yet the embryo might be so well formed and so apparently healthy that no one would suspect syphilis. Dr. Bandler said he could count on the fingers of his hands the children that he had seen that had shown definite signs of syphilis at birth, yet they had been told in college that these children were born with the evidences of syphilis on the palms of their hands and the soles of their feet. These syphilitic children might grow up without definite signs of syphilis; they might only have symptoms of digestive disturbance, a tendency to develop fever easily, or they might simply be delicate and sickly. If the embryo could survive the syphilitic involvement it required more things than one might suppose to affect it. A placenta previa had an abnormal implantation of the placenta and yet he doubted if that made any difference in the way in which the fetus developed. The spermatozoon did not carry syphilis into the ovum. If a woman gave birth to a syphilitic child it was because she herself was syphilitic. It was possible for a man to have syphilis and yet to have perfectly healthy children unless the mother herself was made syphilitic. When it came to alcoholism it was known that alcohol was one poison that injured the embryo and it was also known that alcoholics were not normal individuals, that they were individuals below normal, and consequently they were more likely to become alcoholic than the average person. If, then, the offspring of an alcoholic individual was

defective we attribute it erroneously to the alcoholism of the parent instead of to the defective heredity, although Dr. Bandler said he was of the opinion that alcoholism in the mother had something to do with it. Probably there was a central pathology in these individuals. On whatever line one might study this subject there were two sides; there were the antenatal changes which included the few changes visible in the baby, and when it lived there was the influence that hereditary factors had all through life, even until the individual reached seventy years of age.

Dr. SCHUMANN, in closing, said it was just such questions and speculations as Dr. Bandler had brought forward that showed what they required. The one great need was more data. It had been well said by Dr. Holmes that we should treat the defects of the child by treating those of the grandfather and grandmother. As to the infection of the ovum by the treponema, he had recently looked up the literature and thus far there had been no demonstration of a treponema in the spermatozoon. There was a growing belief that in the life cycle of the treponema there was a granular stage and it had been guessed that possibly the spermatozoa might carry these minute granules into the uterus and thus infect the mother. There was no proof of this, but it was an interesting theory.

SECTION ON MEDICINE.

Stated Meeting, Held April 17, 1917.

DR. HARLOW BROOKS IN THE CHAIR.

The Apparent Dependence of Pathological Variations of the Blood Sugar upon the Diastatic Activity of the Blood.—Drs. VICTOR C. MYERS and J. A. KILLIAN presented this communication. They stated that since Magendie first demonstrated the presence of a diastase or, as it was better known to physiologists, a glycogenase in normal human blood, the various workers in this field had reported results concerning its activity so contradictory that no conclusions, particularly in pathological conditions, were warranted. This contradiction in results unquestionably must be attributed to the lack of a sufficiently accurate method for the quantitative estimation of the activity of the enzyme under all conditions. The procedure the authors had found simplest and most reliable was but another application of the method for the estimation of the blood sugar first introduced by Lewis and Benedict, and later modified by Myers and Bailey. Two 2 c.c. samples of oxalated blood were placed in centrifuge tubes: one was diluted to 10 c.c., the other to 9 c.c., and to this latter tube 1 c.c. of a 1 per cent. solution of soluble starch was added when both tubes had been raised to 40° C. in a water bath. Both tubes were allowed to remain in the water bath maintained constantly at this temperature for fifteen minutes. At the end of this time solid picric acid was added to saturation, the tubes allowed to stand for ten minutes to insure a complete precipitation of the proteins, and then centrifuged and filtered, and the sugar in 3 c.c. portions of the filtrates estimated according to the technique described by Myers and Bailey. The total sugar in the tube to which the starch had been added corrected for the sugar present in the blood and the slight reducing action of the soluble starch, which for any sample remained constant, gave the amount of sugar formed by the diastase in 2 c.c. of blood from the 10 mg. of starch. This quantity expressed as the percentage of the amount of starch added, the writers accepted the figure expressing the activity of the blood diastase under the conditions described. From numerous observations it has been concluded that the activity of the blood diastase toward glycogen was identical with its activity toward soluble starch and further for all samples of blood in their experience, ranging from normal cases to cases of severe diabetes, the 10 mg. of starch formed a sufficient substrate for the action of the enzyme. The figure for the activity of the diastase in normal blood was obtained from the activities in six healthy individuals. The activities in these cases varied between 14 and 17. A large series of miscellaneous pathological conditions were studied and in all of these cases, where a history of diabetes or nephritis could be excluded, and where the blood showed no retention of nitrogeneous waste products nor a hyperglycemia, the activity of the blood diastases never fell below fifteen nor rose above twenty-two. Hence, it might be said that with their method the activity of the blood diastase lay in normal cases between fifteen and twenty, and in pathological conditions it might rise to twenty-five, without indicating diabetes or nephritis. The cases of nephritis examined had been divided into classes—mild cases, where there was a history of albuminuria, a moderate retention of urea nitrogen and of uric acid, a creatinine below five, and a fair phthalein output, and severe cases where there was a marked retention of nitrogeneous products, little or no phthalein output and creatinine above five. In the mild cases there was a moderate hyperglycemia and an increased diastatic activity varying between twenty-one and forty-seven. In the severe cases, all of which proved fatal, the hyperglycemia was more pronounced and the diastatic activity fell between thirty and fifty-one. It was noted that invariably the increase in activity was greater in chronic cases than in acute. Furthermore, in as much as the activity of the diastase in nephritic urines was below normal, the increase in activity in the blood might be due to a retention.

It was in cases of diabetes that they obtained the highest figures for diastatic activity of the blood. In the large series of cases examined the blood sugar ran from 0.23 to 1.23 per cent., and correspondingly, the diastatic activity of the bloods varied from forty-two to seventy-three, that is from three to five times normal. A number of cases were followed over a long period of time, and the blood sugar and the activity of the diastase during this period were represented graphically by curves. In the cases that on treatment showed improvement and left the hospital cured, there was a striking parallelism between the two curves. It was noted also that the activity of the diastase responded more promptly to treatment than did the blood sugar. It was found that the administration of alkali (sodium bicarbonate by mouth) inhibited the activity of the enzyme and when the activity was brought down to normal the diabetic could take carbohydrate without a consequent hyperglycemia. In the case that did not respond to treatment, although the blood sugar was reduced to normal, the activity of the diastase remained high, and whenever the patient received carbohydrate in diet a hyperglycemia resulted. Hence the activity of the enzyme is a more reliable index of the response to treatment than the blood, and consequently it was a prognostic as well as a diagnostic value. Moreover, individuals who gave a history of transient glycosuria or a lowered sugar tolerance showed a diastatic activity of the blood about thirty, therefore an estimation of the diastatic activity of the blood was of greater value in diagnosing latent diabetes than the sugar tolerance test. Many observers had reported a hyperglycemia during general anesthesia. By estimating the sugar, carbon dioxide combining power, and the diastatic activity before and during anesthesia, it was found that the hyperglycemia was accompanied and in all probability caused by an increase in the activity of the diastase with a decrease in the carbon dioxide combining power, indicating a mild acidosis.

Dr. T. STUART HART asked whether there was any parallel between the diastatic activity of the blood and the diastatic activity of the urine. If such a parallel occurred in diabetics and not in nephritics certain conclusions might be drawn as to the difference of the threshold for the excretion of diastase in each of these conditions. In advanced nephritis we have the retention of many substances. Why should we say that the sugar retention was dependent upon the increased diastase in the blood any more than one would say that the increase in the urea nitrogen of the blood was dependent upon the increased blood diastase? Did it not seem more probable that there was a common cause which operated for a retention of all these substances?

Dr. ADOLPH L. RINGER said this was a very beautiful piece of work, but there was one point with which he could not agree, and that was the explanation of the hyperglycemia in cases of nephritis as being due to the fact that there was an increase in diastases. In view of

the power of the normal body to cope with a rise of sugar in the blood and the ease with which it succeeded in getting rid of a tendency to hyperglycemia, he could not believe that hyperglycemia could be explained on the theory of a slight increase in the diastatic activity of the blood. Even where one found an increased diastatic activity and a hyperglycemia he could not say that the latter was dependent on the former unless they ran parallel in all cases; this it seemed from the chart they did not do in every instance. The facts presented, however, were of great value.

Dr. NELSON W. JANNEY stated that it was questionable whether hyperglycemia was to be ascribed to increased diastatic activity in all cases. Thus in experiments with nephritic patients he had repeatedly administered glucose which was followed by a greater hyperglycemia, as shown by hourly blood sugar estimations, than ensued in normal individuals treated in exactly the same way. As in this case, diastatic activity was to be excluded as a cause for this result, it is more likely that the hyperglycemia of nephritis was a retention phenomenon. The blood sugar originated from protein as well as from carbohydrate. Thus the hyperglycemia at times observed in exopthalmic goiter was probably due to sugar formed in toxic protein destruction. Increased diastase in the blood would not be expected here. It would, therefore, be interesting to follow the diastatic activity in such cases in view of this test possibly becoming of diagnostic importance in determining the origin of an increased blood sugar level. We must also bear in mind that no direct proof had yet been brought that the increased diastase in the blood was the actual cause of the hyperglycemia. It might be an accompanying phenomenon. However, the results reported by Drs. Myers and Killian were most striking and suggestive.

Dr. MYERS said that in answer to some of the points brought up he wished to state first that they simply desired to suggest that the hyperglycemia of nephritis might be due to increased diastatic activity. In their earlier investigations (Myers and Bailey) they had not been able to find any explanation of the high blood sugar, although excretion was markedly raised. There might be as much as 0.35 per cent. sugar in the blood and none in the urine. Dr. Ringer had brought up the point that the diastatic activity and the blood sugar did not run parallel in every case. In those cases in which there was a high diastatic activity and a low blood sugar, there was invariably something to explain the discrepancy, as, for instance, a marked restriction in the diet. As to Dr. Janney's point, Dr. Myers said he thought the findings in reference to the diastatic activity fitted in nicely with the results of feeding glucose to nephritics. If we knew the diastatic activity of the blood we could anticipate the type of the blood-sugar curve. Dr. Myers mentioned two cases in which the presence of blood sugar was unsuspected but in which an examination of the blood showed an increased diastatic activity. Upon being questioned these individuals admitted having had sugar in their urine in small amounts at a former time, although at the time of the examination no sugar was present in the urine and the blood-sugar content was essentially normal. This suggested the possibility that the diastatic activity might serve as an early sign of impending diabetes. The rôle of the diastases in the human being and in animals such as the dog and rabbit, is apparently quite different. The diastatic activity of the dog's blood was about twenty times that of the human being, and for this reason animal experimentation along these lines might be of little aid in solving these problems as they affeteed human beings.

Kidney Damage and Recovery after the Acute Fevers.—Dr. ARTHUR BOOKMAN read this paper. He said the effects of acute febrile diseases, and particularly febrile albuminuria, upon the renal function was the subject investigated. Fifteen patients convalescing from typhoid fever, pneumonia, tonsillitis, malaria, typhus fever, staphylococcus meningitis were studied. Most of the tests were made from three to fifteen days after the temperature had become normal. Two patients were followed for several months after recovery. Of special interest was the results obtained on the phenolsulphonephthalein excretion, and the estimation of the renal function by the Mosenthal-Schlayer technique. The majority of the patients had a lower thalein output. Over one-half on the test diet had some nocturnal polyuria. The total output of salt was low in the majority of the cases, and the question was raised whether the excretion of sodium chloride during pneumonia and other acute febrile diseases was not largely due to lowered kidney function. The importance of the repeated functional test was emphasized. The renal function might be very much impaired without albuminuria or other common signs of nephritis. The interpretation of the results of the tests of renal function and the influence of preceding febrile diseases must always be considered.

Dr. CHARLES E. QUIMBY said that with reference to chloride retention in defective kidney function the chloride was not necessarily retained in the blood, but was thrown out through the lungs in pneumonia into the spinal fluid in meningitis. Again the pneumococcus was only destroyed in the presence of chloride. Dr. Quimby said he was not going to admit that the impaired kidney function was due to inability to excrete primarily; it was a question of impaired metabolism back of the kidney that was involved, and that was why he had taken up a study of the problems of metabolism. He believed that impaired kidney function was primarily a question of metabolism and he hoped this would be proved to be the truth, for it was in this direction that the hope of therapeutics lay.

Dr. A. A. EPSTEIN said he also was inclined to believe that there was a form of nephritis dependent upon primary metabolism and that they sometimes got a picture of impaired kidney function for which the kidney was not responsible

Dr. BOOKMAN said that in regard to chloride retention in the lungs in pneumonia the point he had raised was with reference to chloride excretion as an indication of impaired kidney function. In typhoid fever and malaria the cases of which he studied, there was very much more sodium chloride retention than in pneumonia. This work had a double bearing. It told not only about the function, but it told about the reliability of the individual tests, and he believed that work of this kind would help us arrive at a final judgment as to the reliability and availability of tests of renal function.

The Interpretation of Urea Nitrogen Estimations in the Blood in Various Kidney Lesions.—Drs. JOHN LARKIN and I. J. LEVY presented this communication, which was illustrated by lantern slides. They stated that in studying the renal causes for nitrogen retention they had not forgotten that the extrarenal factors for such retention must be given due consideration. The first and most important of these was diet; second, certain metabolic conditions, which were little understood at the present time; third, they had observed in cases of edema with marked diuresis that there was a tendency for the nitrogen content of the blood to increase, but it soon returned to the normal limit after the elimination of the fluid; fourth, in some cases just before death, irrespective of the type of kidney lesion, in fact in fairly normal kidneys, there was definite rise in the nitrogenous elements of the blood. Many cases were loosely diagnosed as nephritis which were not, *per se*, nephritic, and pathological changes in the kidney were designated with such ambiguous terms as "interstitial nephritis," "parenchymatous nephritis," etc. These terms gave no inkling as to the type of nephritis meant. No wonder, therefore, with a diagnosis of interstitial nephritis one obtained all sorts of nitrogenous estimations in the blood in this type of lesion. With these facts in mind they had found it necessary to adopt a classification in which the clinical diagnosis could be checked up with a fair degree of uniformity with the pathological findings. They had therefore adopted the essentials of the Vollhart and Fahr classification: First, the glomerular type; second, the arterial type, and, third, the tubular type. The glomerular type they had designated as glomerulitis and had subdivided into acute and chronic. The acute type, which was a definite clinical entity, was characterized by a true inflammatory reaction, exudation, swelling of the epithelium of the tuft, increase of cells in and upon the tuft. This was a lesion which might go on to repair and in fact usually did. This accounted for the fact that it was seldom seen at the autopsy table. The chronic type was characterized by the fact that the kidney lesion was beyond repair. It might begin with an acute onset

and run its course in a few months; or with an insidious onset, which might not present any marked evidence of trouble until years later. Most of these cases died of true uremia. The glomeruli presented inter- and extracapillary changes, some having gone on to various stages of hyalinization. The blood vessels became secondarily involved. The interstitial and tubular changes were secondary to the arteriosclerosis. If the arterial and interstitial changes were marked, we had the socalled contracted kidney. With one exception, in acute glomerulitis there was no increase in the nitrogen retention in the blood. In some cases, as in scarlet fever, after anesthesia, anoliguria might be so extreme that the nitrogen increased in proportion with the degree of retention and the length of time it was present. In acute glomerulitis convulsive seizures were seen at the onset or during the course, but were independent of true uremia in that the patients recovered, and during the period of the attacks or months later, when they were apparently in good health, the nitrogen in the blood was within normal limits. When these seizures occurred in the course of chronic glomerulitis the nitrogen in the blood was definitely increased. It was a fair conclusion, therefore, that the nitrogen estimation in the blood in socalled eclamptic uremia was of great prognostic importance and differentiated an acute glomerulitis with a favorable course from a chronic glomerulitis with an unfavorable prognosis. Of 12 cases of chronic glomerulitis observed by the authors, 8 had died and 4 were living. The nitrogen estimation in this group gave varying results. In the advent of uremia there was a distinct and marked increase in the blood nitrogen, the amount increasing until death. Normal nitrogen estimations might be found in cases with intra- and extracapillary glomerular changes in the kidney. In an attack of eclamptic uremia in which there was an increase in the nitrogen content of the blood they had found, with few exceptions, that if the estimate on successive days showed definite increase, the patient was gradually passing into a condition of true uremia and the immediate prognosis was unfavorable. If, however, the successive estimations gave a lowered reading, the immediate prognosis was more favorable. An increase in the nitrogen content of the blood in the course of a chronic glomerulitis generally was a bad prognostic sign. The patients succumbed, probably within a few years, most of them in a much shorter time. Illustrations of the three types of chronic glomerulitis were presented. In the first type the kidney presented a picture of severe extracapillary glomerulitis, hardly a normal glomerulus being seen in the section. The parenchyma was replaced by fibrous connective tissue, with areas of round celled infiltration. The second illustration was of the typical contracted type. Practically every glomerulus in the section had undergone hyalinization as the result of earlier inflammatory changes in the glomeruli. There was dense connective tissue replacement and arteriosclerotic changes. The third type of chronic glomerulitis presented had occurred in the course of an acute infectious endocarditis. This showed the glomerular changes and normal nitrogen figures. Some glomeruli showed distinct inflammatory reaction, others were fairly normal; there were some interstitial changes. In the second type under this classification, the arteriosclerotic kidney, the changes found were those primarily of vascular origin, the glomeruli and parenchyma becoming secondarily involved, depending upon the grade of arteriosclerosis. The various grades of atrophy and hyalinization of the glomeruli and moderate or marked interstitial changes could be seen, depending upon the age of the patient and the severity of the process. The end result was the socalled primary contracted kidney. The patients did not die of their kidney lesion, but from arteriosclerosis, cardiac failure, apoplexy, or an intercurrent affection. There were 15 cases in this series, all with autopsy findings. The blood nitrogen during the course of the disease gave normal readings. Twenty-four to forty-eight days before death there was marked increase in the nitrogen content of the blood. The markedly arteriosclerotic kidneys gave a much higher figure. Ten to fifteen days before death, however, there was a definite increase in the nitrogen content of the blood in cases with marked arterial changes, but how soon this change became apparent they were not prepared to say. In kidneys with mild sclerotic changes there was very little rise in the nitrogen content. In the third type, the tubular or socalled nephritic kidney, usually diagnosed by edema, the focus of involvement was in the convoluted tubules. The clinical symptoms associated with this type were due to extrarenal causes. There was a characteristic fatty degeneration of the tubules, which was doubly refractive. There were no glomerular changes, unless this was an added complication, and the blood nitrogen was within normal limits. Extrarenal factors were of paramount importance in interpreting nitrogen readings in the blood.

Dr. T. Stuart Hart said that he had been much interested in the paper of Dr. Larkin. Dr. Larkin was fortunate in finding kidneys which represented comparatively such distinct types. Dr. Hart had been able to study the kidneys in a considerable number of cases of nephritis in which, during life, very careful studies had been made of the constituents of the blood and the functional activities of the kidneys. He had been unable to correlate the changes in function made out during life with the pathological condition found at autopsy. The difficulty seemed to be that the terminal changes which one saw in the kidney at autopsy did not show a single distinct type of structural change; the condition was so far advanced that practically all the kidney structures were more or less involved and it was almost impossible to tell which one of these structures was the first to show a pathological change.

Dr. Ringer said we might have very marked disturbance in the kidney without getting any changes in the blood whatever, and the reason was that the factor of safety in the kidney was very large. We might remove one kidney and a part of the other and yet get no disturbance in the blood. The same was true with reference to the pathology. We might find a large part of the kidney tissue destroyed and yet get no signs of decompensation by the functional tests. Until we have worked out a method to find the maximum function of a kidney we could not know anything definite of the pathology. The chemistry of the blood might be normal in the presence of nephritis, and we have no means of telling the degree of kidney destruction until there is beginning of decompensation. The term uremia should be reserved for those conditions in which we find a damming back of products of metabolism and an increase in the concentration of urea in the blood. When patients with nephritis went into coma or had convulsions, and did not show any increase in the nonprotein nitrogenous constituents of the blood, we should look for other causes and not call them cases of uremia.

Dr. Levy, in closing the discussion, said that in regard to nephritic kidney they had had but one case of this kind that came to autopsy. In this instance the man had lost from eighty to ninety pounds and had died of an unusual metabolic disturbance. As to the diagnosis of the terminal sclerotic type, this could usually be distinguished from the terminal glomerular type by the two hour concentration test and studying the water elimination. Sometimes there would be something in the history suggestive, as a tonsillitis, that would point to the glomeruli as causing the kidney disturbance, and the finding of a normal blood nitrogen reading would be of assistance. In marked sclerotic kidneys where there was very little parenchyma one might get normal nitrogenous findings and some glomerular changes, but all the changes were secondary to the arterial changes; it was in just this type of kidney that one got normal nitrogen findings until ten or fifteen days before death. In regard to calling the convulsive seizures of the glomerular type of kidney eclamptic uremia, they admitted that was a bad term, because the seizures were not due to nitrogen retention but to some extrarenal cause. The blood pressure during these seizures is usually between two and three hundred mm., so that the convulsion would seem to be due to edema of the brain, which was the result of the increased blood pressure, and not to any retention of nitrogen.

The Rôle of Splanchnic Stasis in Atony of the Alimentary Canal.—Dr. Fenton B. Turck read this paper. He stated that prevalent as were disorders of the gastrointestinal tract, they were the least understood

of all ailments by both the internist and the surgeon. If the phenomena underlying these conditions were understood and viewed in the light of functional disturbances and altered motility, as dependent upon dynamics rather than as anatomical or morphological abnormalities, fewer of these cases would reach the surgeon and fewer surgeons would make the confession recently made by Temoin, who said, "The return of symptoms after gastroenterostomy or stomach resection are of such frequent occurrence that I now make it a practice to do an extensive resection." An understanding of the etiology of gastrointestinal disturbances would explain the phenomenon of dilatation and the surgeon would no longer ask the question, "How a stomach with two openings, the patent pylorus and a working gastroenterostomy at the most dependent part of the stomach, could be so distended with fluid?" The surgeon would, if he understood the fundamental causes of these conditions, operate only for mechanical obstruction and not for functional resistance. Dr. Turck reviewed experimental work which he had from time to time presented which showed that changes in the intestinal wall resulting from alteration in the blood supply increased the permeability of the mucosa to microorganisms, and that the colon group seemed more capable of migration than many other forms of intestinal bacteria. He described the diffusion of bacteria from the intestinal tract and discussed the conditions predisposing to the migration of bacteria and other proteins. He showed the influence of shock, fatigue, obstruction, stasis, atony, and overfeeding in lowering the bacteriolytic function of the submucous zone of the intestinal wall. He dwelt on the part played by hypersensitization of the muscle cells predisposing or preparing them for anaphylactic reaction which was bound to take place when the bacteria and colloidal proteins were brought into the area of these sensitized cells. Such a hypersensitive status of the muscle cells might be hereditary and was resident in the cells and not in the fluids of the body. He related his experiments in feeding animals with bacteria, irritants, and food in large amounts, and showed the effects of meat extractives and fatty acids, both of which favored splanchnic congestion and the diffusion of bacteria. All the factors considered were operative in establishing a vicious circle and in maintaining it. It should therefore be borne in mind that if treatment in these conditions was to be effective it must consist in a combination of methods directed to the various causes operative in the production of the pathological condition. Treatment must first be antianaphylactic; secondly, it must be biological, and, thirdly, it must be physiological. In establishing antianaphylaxis atropine sulphate and a combination of calcium chloride, calcium lactate, and calcium carbonate had proven effective. If the anaphylactic status was due to a food idiosyncrasy, that would have to be treated in the accepted manner for overcoming such a condition, by the administration of the particular article of food that was causing the trouble in very small doses until a tolerance was established. The biological treatment was an important factor and consisted of the autogenous vaccines made from a combination of the organisms derived from the patient's feces, urine, and stomach contents and grown on his own blood serum. The physiological treatment consisted in colonic and gastric lavage for the relief of tension and the production of intergastric hyperemia; the institution of intergastric and intercolonic pneumatic gymnastics and a system of physical exercises which had been shown to be effective in diminishing the amount of blood in the splanchnia area by driving it to the peripheral parts of the body. In the dietetic treatment, Dr. Turck emphasized the importance of avoiding meat extractives and fatty acids and of administering only two meals a day rather than the more generally accepted plan of frequent and small feedings. (See MEDICAL RECORD, June 24, 1916.)

Dr. T. STUART HART said that Dr. Turck had covered such a wide field that it was difficult to select any one point for discussion. There was one point of similarity in the change which had taken place in recent years in the viewpoint held in regard to the heart and the viewpoint which Dr. Turck had presented in regard to the abdominal veins. Nowadays the theory was pretty well accepted that in the activities of the heart, the muscle cell was the important element; the nerve mechanism the less important. In other words, the myogenic theory was replacing the neurogenic theory. Dr. Turck had said very little about vasomotor influences, but much more of changes in the muscle cells of the walls of the blood vessels. Of course, as in the case of the heart, the correctness of the myogenic theory was still not absolutely settled, but we had found that this point of view of looking on the changes in the muscle cells, as the fundamental thing, gave us an hypothesis which was exceedingly valuable as a practical working basis. Dr. Turck had given some very striking evidence suggestive of the effect of changes in the muscle cells similar to the conditions which Dr. Longcope had described in anaphylactic shock. Some years ago, Popielski, while studying the effect of Witte's peptone in relation to anaphylaxis, was able to isolate a substance which was not peptone proper but was extremely poisonous and acted, he though, mostly on the blood vessels. So prominent was this feature that he proposed for it the name *vasodilatin*. It was universally agreed that in anaphylactic shock the heart was not at fault. It did not give out, but instead there was probably a dilatation of the small peripheral vessels so that the subject was practically bled into the veins of the abdomen. These questions were not purely of academic interest. The subject had a most important practical bearing. He felt that we had been grouping many cases under the term of nervous exhaustion when, as a matter of fact, the patients were suffering from exhaustion of the muscle cells; we had called them neurasthenics; they were probably in a large measure myasthenics.

Dr. RUSSELL CECIL said he was much interested in Dr. Turck's interpretation of the changes in the intestinal walls as possibly due to some form of anaphylaxis. Friedberger and Victor Vaughan have both shown that it was possible to sensitize animals to bacteria. Weil had shown that anaphylaxis was largely a cellular phenomenon. He showed that in anaphylaxis in guinea-pigs and dogs a destruction of the liver cells took place very much like that shown by Dr. Turck in the cells of the intestinal wall. It would be interesting to know whether the changes which Longcope described in the liver and kidneys after repeated anaphylactic shocks were shown in the muscle cells of Dr. Turck's cases. Dr. Cecil said he was interested in hearing what had been said about the colon bacillus and the fact that this condition could be produced by prolonged feeding with this organism. He wondered if the same condition could be produced by feeding the animals with other kinds of bacteria.

Dr. TURCK stated that there were usually other bacilli in symbiosis with the colon bacilli.

Dr. CECIL said Dr. Turck had not told them much about his technique. Some of the changes that had been shown were often seen in tissue that had undergone autolysis before fixation. Unless some such error of technic had caused the autolysis it was evidently possible for bacteria to diffuse through the mucosa and to produce destruction of the smooth muscle cells.

Dr. C. C. LIEB stated that smooth muscle was capable of carrying out contractions only when it received impulses from the nervous system. Apparently peristalsis was a perfectly coordinated act and it would be impossible to have a contraction unless Auerbach's ganglia was intact. Another interesting thing was that it seemed that experiments done by Magnus showed that peristalsis went on quite independently of Meissner's plexus and one got a perfectly typical peristalsis on isolated intestine. This would suggest that the action of the bacteria was not of vital importance so far as the changes that are effected by Auerbach's plexus. Dr. Lieb said that of course he was speaking of true stimulation and relaxation and not considering the segmental movements described by Cannon; such movements were due to tension and were brought about by distention. The more smooth muscle was distended the greater was likely to be the effort at contraction, and this increased as the optimum tension was approached. When the optimum tension was reached the muscle weakened and relaxation followed. Contraction was out of the question in some of Dr. Turck's specimens taken from dogs.

Dr. Charles E. Quimby said he thought they should not lay too much stress on toxins or any other one factor. Arterial contraction had been spoken of; if there was some back pressure in the veins and there was a bit of slowing of the circulation there would be interference with nutrition, and one then got the effect of the bacteria and their toxins. The blocking of the circulation had as much to do with the production of the effect as the other factors. Withdrawal of food or restricted diet did not interfere with the nutrition of the muscle cells of the stomach wall because these derived their nutrition not directly from the food in the stomach but from other parts of the body. By washing out the stomach and removing the pressure one got a response of the exhausted muscle.

Dr. Turck said in closing that, as Dr. Hart observed, the involuntary muscle cells showed distinct lesions in both experimental and clinical work on the heart and circulation, so in dilatation of the alimentary tract, both acute and chronic, the primary cause was found to be due to physico-chemical changes in the unstriated muscle cell. These lesions, as the speaker had demonstrated, in muscle cells were the direct cause, not hypothetical "nervous exhaustion." Acute dilatation of the stomach and intestines associated frequently with "shock" had been assumed to be of nervous origin. In shock Crile attempted to prove the "nerve exhaustion theory," but Kocher, and also according to Smallwood and Phillips, by carefully controlled experiments, concluded that this was "a nerve assumption." Duchesschi showed by isolation of the stomach and intestines from all nerve influence that the motor power of the stomach and intestines resumed normal activity. Dr. Turck stated that he had shown that in both acute and chronic conditions the muscle cells underwent degeneration by "toxic" influence or anaphalactic reaction resulting in atony and dilatation. Since his earlier publications in 1897-1899 and 1903 he had made many experiments and clinical observations which were being better understood in the clinical relations to the great number of symptoms classed as "neurasthenia" and supposed to be due to some obstruction by "kinks" and other assumed causes, which we now found were primarily muscle degeneration, sometimes designated as Zenker's degeneration of fatigue. Dr. Lieb, who had done such excellent work on unstriated muscle, recognized the important rôle of the muscle cell in work and fatigue. While the nerve ganglion aided in coordinating the muscle cells capable of independent rhythmical motion, as soon as the muscle cells underwent these changes with disturbance of the venous splanchnic area we had clearly defined pathologic physiology to be corrected by physiological and biological methods. The point raised that the starvation method (to inaugurate treatment) might cause muscle degeneration, was not founded on fact. It must be remembered that the animal or patient fed on his reserve fat during starvation, and when this was finally exhausted the voluntary muscles were utilized, not the visceral involuntary muscle cells.

Gas Edema in a Woman.—Kummer reports the case of a woman of forty kicked in the right leg by a horse. She escaped fracture. In forty-eight hours she showed edema of the entire extremity and part of the trunk. Death occurred from collapse. The vibrio of sepsis was found in cultures.—*Revue médicale de la Suisse romande.*

Brudzinsky's Sign.—This is produced as follows: One of the inferior extremities is flexed, the leg upon the thigh and the latter upon the pelvis so that it rests upon the abdomen. In meningeal affections this maneuver causes a reflex movement of the thigh of the opposite side, either of flexion or extension upon the pelvis. It may be necessary to flex the thigh with the leg in extension.—*Policlinico.*

Elimination of 606.—Strzyzowski states that neosalvarsan-Ehrlich, novarsenobenzol-Billon and Gálvl-Mouneyrot are identical for all practical purposes. A preparation known as Danysz-102, which contains antimony and silver, is said to be superior throughout to the arsenic synthetics. As far as priority goes, Bechamp was the first to prepare anilarsenic acid in 1863. Its sodium salt, known as atoxyl, was introduced in 1902.—*Revue médicale de la Suisse romande.*

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

The Starvation Treatment of Diabetes, with a Series of Graduated Diets. By Lewis Webb Hill, M.D., and Rena S. Eckman, with an introduction by Richard C. Cabot, M.D. Third Edition. 134 pages Published by W. M. Leonard, Boston, Mass. 1917.

Clinical Studies in Epilepsy. By L. Pierce Clark, M. D. 151 pages. Illustrated. Published by State Hospitals Press, Utica, N. Y. 1917.

The Twenty-Third Annual Report of the Managers and Officers of the Craig Colony for Epileptics, Sonyea, Livingston, Co., N. Y. 128 pages. Illustrated. Published by the J. B. Lyon Co., Albany, N. Y. 1917.

The Institution Quarterly. Vol. VIII, No. 1, March 31, 1917. Illustrated. 231 pages. Published by The State Board of Administration, The State Charities Commission, The State Psychopathic Institute, Springfield, Ill.

The Internal Secretions, Their Physiology ani Application to Pathology. By E. Gley, M.D. Trans lated from the French and edited by Maurice Fishberg, M.D. 241 pages. Price, $2.00 net. Published by Paul B. Hoeber, 69 East 59th Street, New York City.

Les Psychonevroses de Guerre. Par G. Roussy et Jean Lhermitte. 187 pages. Illustrated. Price 4 fr. Published by Masson & Cie., Paris, 1917.

Traitement et Restauration des Lésions des Nerfs. Par Mme. Athanassio-Benisty. Preface du Professeur Pierre Marie. 178 pages. Illustrated. Price, 4 fr. Published by Masson & Cie., Paris, 1917.

Les Fractures de la Machoire Inférieure. Par M.M. Leon Imbert et Pierre Real. 151 pages. Illustrated. Price, 4 fr. Published by Masson & Cie., Editeurs, Paris, 1917.

Localisation et Extraction des Projectiles. Par L. Ombredanne et R. Ledoux Lebard. 346 pages. Illtrated. Price, 4 fr. Published by Masson & Cie., Paris, 1917.

Forty-Fifth Annual Report of the Roosevelt Hospital, New York. 1916. From Jan 1, 1916, to Dec. 31, 1916. Exclusive of Medical and Surgical Statistics. 64 pages. Illustrated.

Physical Chemistry of Vital Phenomena for Students and Ivestigators in the Biological and Medical Sciences. By J. F. McClendon. 240 pages. Illustrated. Price, $2.00 net. Published by Princeton University Press, Princeton, N. J. 1917.

Textbook of Ophthalmology. By Hofrat Ernest Fuchs. With 462 illustrations and 1067 pages. Price, $7.00. Published by J. B. Lippincott Co., Philadelphia and London.

Botanic Drugs. Their Materia Medica, Pharmacology and Therapeutics. By Thomas S. Blair, M.D. 394 pages. Price, $2.00. Published by The Therapeutic Digest Publishing Co., Cincinnati, Ohio. 1917.

Medical State Board Questions and Answers. Fourth Edition. Thoroughly revised. By R. Max Goepp, M.D. Octavo volume of 724 pages. Cloth, $4.25 net. Published by W. B. Saunders Co., Philadelphia and London. 1917.

The Practical Medicine Series. Comprising Ten Volumes on the year's progress in Medicine and Surgery, under the general editorial charge of Charles L. Mix, A.M., M.D. Volume I, General Medicine. Edited by Frank Billings, M.S., M.D., assisted by Burrell O. Raulston, A.B., M.D. Series 1917. Price per volume, $1.50. Price of the series of ten volumes, $10.00. 383 pages. Illustrated. Published by The Year Book Publishers, Chicago, Ill.

The Sense of Taste. By H. L. Hollingworth, Ph.D., and A. T. Poffenberger, Jr., Ph.D. 200 pages. Price, $1.25 net. Postage, 12c. Published by Moffat, Yard & Co., New York City. 1917.

A CONTRIBUTION TO THE HISTOPATHOLOGY OF HUMAN AND EXPERIMENTAL POLIOMYELITIS.*

By G. B. HASSIN, M.D.,

CHICAGO.

ATTENDING NEUROLOGIST, COOK COUNTY HOSPITAL.

The histopathological changes in acute anterior poliomyelitis are not always the same. In an old case where the onset of the disease dates back many years they will be different from those to be found in a recent case of but a few days' duration. Prior to Rissler's[1] investigations the histopathological studies of this disease were carried on on old cases (Cornil,[2] Prévost,[3] Charcot and Joffroy,[4] Parrot and Joffroy[5]), the youngest case having been that of Damaschino and Roger,[6] two months old. As early as 1878, W. Erb[7] wrote: "We have a right to demand that only the most recent cases obtainable should be examined, with a view to determining the true essence of the pathological process present. Cases which are examined from 20 to 60 years after the first attack certainly cannot give safe and positive data for judgment with regard to this disease."

Since Erb wrote these lines numerous reports appeared on the pathology of recent cases of this disease, the latest and most exhaustive ones being those by Wickman,[8] Harbitz and Scheel,[9] Strauss,[10] Pettersson, Kling and Wernstedt,[11] and Walter.[12] The general conclusion arrived at by the various authors is that in fresh poliomyelitis cases there are present vascular, or interstitial, and parenchymatous changes. The former are to be found in the entire nervous system and the meninges, the latter in the ganglion cells of the gray matter of the anterior and less so of the posterior horns. Parenchymatous changes in the white matter and glia are recorded completely only by Walter[12] and partially by Kling, Pettersson, and Wernstedt,[11] but are ignored even in the classical works of Wickman, Harbitz, and Scheel. Further, it was found that the poliomyelitis virus does not confine its activity to the substance of the spinal cord only, but may also affect the substance of the medulla, of the brain proper, giving rise to clinical pictures known in the literature as bulbomyelitis, encephalitis, polioencephalitis anterior, etc. Finally successful inoculations of various animals with this disease enable one to study the pathological changes on very fresh material and compare them with those found in human beings. These three problems—poliomyelitis in fresh human cases, poliomyelitis with the cerebral localization, and experimental poliomyelitis in various animals, I had the opportunity to study on the material of Cook County Hospital and its pathology laboratory. In my studies I paid much attention to the parenchymatous changes not only of the gray matter but also of the white substance and to possible changes in the glia. Altogether 15 cases have been studied chiefly with the methods used by the Alzheimer school. Of these 15 cases four were human, four in rabbits (two of which were inoculated with Shiga bacilli), two in monkeys, and five in sheep. In some of these cases only the spinal cord was studied, in some both the brain and the spinal cord were examined, the experimental animal material having been kindly furnished to me by Drs. John Nuzum, M. Herzog, and F. Francis.

To avoid repetitions I will report in detail but one case, the most typical one, and of the others I will give just the necessary findings.

Case I.—DuL, man, 26 years old, a salesman by occupation, entered Cook County Hospital on August 23, 1916, with paralysis of all four extremities, shortness of breath, speech disturbances, and stiffness of the neck. The disease lasted about three weeks and started with a severe "cold." The patient was coughing, had a headache and fever. About seventeen days after the onset he began losing power in the left upper limb which became the next day totally helpless. Three days later, August 20, the right arm became paralyzed, during the following two days the lower limbs were involved, and on August 23, only the toes could be moved. During the last few days there was difficulty in breathing and talking. There was no pain or numbness. Previous history: malaria, measles, and gonorrhea.

Examination: Inability to move the extremities. The respiration is shallow, accelerated; the skin hot, the face flushed, conjunctivæ injected, speech indistinct, mentality preserved. The pupils were equal, normally reacted to light and accommodation. The limbs were in a state of flaccid paralysis with the loss of all the tendon reflexes, while the abdominal and the pharyngeal reflexes were present, the plantar absent. Spinal puncture: pressure increased, 70 cells, positive Nonne. The temperature (rectal) was 102°. Urine normal, pulse 120, respiration 46. The patient died the next day, and autopsy was performed one hour after death by Dr. John Nuzum.

Findings: Macroscopically there was a marked passive hyperemia of the pia-arachnoid over the cerebral cortex and of the spinal leptomeninges; the spinal fluid was turbid.

For microscopical studies only the dorsal region was available and the motor area of the brain, as the rest of the nerve tissue was used for experimental work by Drs. Nuzum and Herzog. The cellular changes and infiltrations were studied with hematoxylin-eosin, toluidin blue (Nissl's method), methyl green-pyronin, Alzheimer's methods VI (acid fuchsin-lichtgrün) and IV (hematoxylin (Mallory's) and copper acetate). The gray and the white matter of the spinal cord appeared under the low power, vacuolated, cribriform, the anterior horns were quite swollen and increased in volume. They contained numerous foci of infiltration, hyperemic

*From the Pathological Laboratory of Cook County Hospital.

and dilated blood vessels, and foci of necrosis. The foci of infiltration were especially numerous in the ventromedial and ventrolateral portions of the anterior horns, and were diffuse as well as perivascular. The latter occupied the so-called adventitial lymph spaces of Virchow-Robin, and mainly consisted of lymphocytes and few leucocytes; plasma cells, so-called "Stäbchenzellen" and Maximow's polyblasts were but occasionally present. The parenchyma of the gray matter was covered with numerous cells that in some places formed dense masses, and the perivascular infiltration was so pronounced that it sometimes caused occlusion or obliteration of the vascular lumen. The infiltration was also quite pronounced in the posterior horns and in the white matter, where it was confined to the bands of the connective tissue carrying the infiltrated vessels, but the parenchyma, i.e. the white substance itself, was spared, being free from infiltrations.

The ganglion cells of the anterior horns showed, as a rule, profound changes. Some cells appeared somewhat swollen, without any Nissl bodies, or showed the latter in the form of dust. The nucleus was densely stained, pycnotic. Pycnosis and chromatolysis thus were the principal changes in the ganglion cells. Other cells appeared shrunken, eaten away, and infiltrated by various cells—neuronophags. The latter consisted, in little damaged cells, principally of glia cells, but in those, with far gone destruction, other varieties, as leucocytes, etc., could be found. As a rule, very few ganglion cells could be found in the gray matter of the anterior horns, and in some places it was possible to find only fragments of ganglion cells surrounded by a mass of neuronophags of various types.

The foci of necrosis were mainly confined to the medial portion of the anterior horns. One focus was adjacent to the right posterior horn and formed a cavity.

The condition of the white substance and the glia was well shown on specimens stained with Mann (methyl blue-eosin), Bielshowsky, Marchi, and combined Marchi-Mann stains.

The dendrites of the anterior horn cells were uniformly swollen, greatly increased in size, the axones also swollen, tortuous, and club-shaped in many places. In some areas the myelin was broken up in globules, but as a rule it was retained, and well preserved in every column of the spinal cord. The glia tissue was rich in small protoplasm-poor glia cells scattered among dense glia fibers. Some glia cells had large protoplasmic bodies, frequently containing vacuoles, which on Marchi-Mann specimens showed the presence of minute particles of fat.

In the marginal glia some glia cells were large, homogeneous in appearance, devoid of any processes, but with a densely stained, pycnotic nucleus—so-called ameboid glia. As a whole, the central portions of the white substance, around the gray matter, appeared more involved than the external, marginal area, where a normal array of the axones, myelin, was present. The meninges showed hyperemia and infiltrated vessels. The infiltration consisted mostly of lymphocytes. The brain changes, though present, were considerably milder than in the spinal cord. Thus, the ganglion cells of the brain showed a slight chromatolysis, vacuolated bodies, absence sometimes of their processes, but none showed neuronophagic phenomena. The vessels appeared sometimes hyperemic, but without any infiltrations, and the glia showed no changes whatever.

This case was clinically one of Landry's paralysis, of the descending type; pathologically it was a typical poliomyelitis. The pathological changes were found in the spinal cord and somewhat in the brain tissue and also in the meninges. They were very much pronounced in the latter as well as in the gray matter of the spinal cord; were slight in the white matter, and marked in the glia (ameboid transformation). The changes were thus both parenchymatous and interstitial, and especially severe in the gray matter, where they resulted in formation of necrotic foci, while the white matter changes were comparatively insignificant. An emulsion from the spinal cord and the brain of this patient (and of other patients) injected in monkeys caused a poliomyelitis, and in the spinal fluid there were found by Nuzum peculiar diplococci, which are evidently specific for this disease.

This case furnishes additional proofs that Landry's paralysis is most probably a form of poliomyelitis, as suggested by Wickman, Harbitz, and Scheel, and pathologically proven long ago, among others, by Dr. Bassoe.[13]

Case II.—Fr. A., 2 years old, entered Cook County Hospital, August 28, 1916 (service of Dr. Francis) in a drowsy state, helplessly lying on his back. No history could be obtained. There was marked paresis of all the muscles of the neck, total paralysis of the shoulder muscles, and a bilateral páresis of the muscles of forearms and hands. The muscles of the lower limbs were either totally paralyzed (adductors of the thighs, extensors of the legs), or merely paretic. The skin was universally hypersensitive, and active movements of the limbs, neck, and back were very painful. The patellar, tendo Achillis, and abdominal reflexes were lost; the plantar, biceps, triceps, as well as Kernig and Babinski, clonuses were absent. Rigidity of the neck and back was also absent. The spinal fluid was under increased pressure, with 35 cells per cmm., and negative Nonne. The patient developed convulsions the next day, and died the following day in spite of intravenous and intraspinal injections of convalescent serum and diphtheria antitoxin. The postmortem was made while the body was still warm by Dr. John Nuzum. There was found marked hyperemia of the pia-arachnoid membrane over the cortex, the brain stem, and the lateral surfaces of the spinal cord. There was slight edema of the brain and spinal cord, a purulent nasal discharge, and a hyperemic state of the viscera. As the largest portion of the brain and spinal cord was secured under sterile conditions for cultures and animal inoculations, I could obtain but a small portion of the brain which was partly hardened in 95 per cent. alcohol (for Nissl stain) and partly in 10 per cent. formalin for glia stain (Mann's mixture). The spinal cord changes were followed up on hematoxylin-eosin specimens kindly furnished to me by Dr. Nuzum.

The cerebral meninges showed hyperemia, dilated vessels, and very mild vascular infiltrations. The brain tissue itself appeared cribriform, with enlarged pericellular and perivascular spaces; the vessels were slightly hyperemic, but very few showed infiltrations. The Mann stain showed a very mild glia reticulum. The ganglion cells, however, were deeply changed. Their cell bodies, in many instances, were reduced to mere fragments surrounding a very large chromatin-rich nucleus. The Nissl bodies were totally gone, and in some cells even the nucleus was dissolved, a mere nucleolus remaining of a former neucleus. Very few cells showed distinct processes which usually were very thin and granular in appearance. The changes mainly consisted in total disintegration of the protoplasm of the ganglion cells and caryolysis. Proliferation of the satellites, neuronophagia, vascular and marked glia changes were absent. The most proper pathological diagnosis in this case would be degenerative encephalitis. In the spinal cord there was in evidence a paucity of ganglion cells, some of which appeared to be normal, some showed neuronophagic phenomena. The cellular infiltration was diffuse and perivascular, and consisted of lymphocytes, very few leucocytes, plasmacells, and polyblasts. The pia showed marked infiltration, especially in the anterior fissure. The white matter and the posterior horns showed hardly any infiltrations which were exclusively confined to the vessels.

The microscopical picture of the spinal cord in this case was that of poliomyelitis, that of the brain a degenerative encephalitis, which, however, was not very marked. The condition of the parenchyma of the white matter could not be ascertained, as the proper methods could not be employed. The most prominent features, however, were some paren-

chymatous changes in the gray matter of the spinal cord and the brain, coupled with pronounced vascular changes in the anterior horns. In the white matter even the vascular, or interstitial, changes were quite insignificant.

This case, clinically a typical poliomyelitis, pathologically shows almost exclusively ganglion cell changes in the brain tissue, aside from the pronounced infiltrations of the vessels of the anterior horns and hyperemia of the pia-arachnoid.

Case III.—G. W., age 24, entered the Cook County Hospital, September 12, 1916, in a dying condition. Was sick but one day; had repeated vomiting and convulsions. Respiration—shallow, labored, and rapid. The head was turned to the left with the eyes diverted to the right. The left arm and leg were in a condition of spasticity, while the right leg and arm were flaccid, with the los of reflexes; the left patellar reflex was exaggerated; the abdominal reflexes were lost. Death occurred fifteen minutes after entrance to the hospital. Postmortem was made twenty-five minutes after death by Dr. J. Nuzum.

The macroscopical findings were marked hyperemia of the pia-arachnoid, moderate hyperemia of the gray matter of the spinal cord; encapsulated abscesses in both tonsils.

Microscopically there were insignificant vascular or perivascular changes, the infiltration having been presented by but one row of cells (lymphocytes). Many ganglion cells in the anterior horns were preserved, had a normal configuration, and normal size; Nissl bodies and processes were clearly present. Some cells appeared shrunken, invaded by "neuronophags," mostly glia cells (protoplasm poor); other cells appeared vacuolated, and some were represented by mere fragments surrounded by neuronophags; some again, though normal in appearance, were greatly swollen, with Nissl bodies in the form of dust. The central canal was markedly dilated, with a regular arrangement of the ependyma cells. The spinal ganglia showed no changes, the meninges presented a moderate cellular infiltration. The posterior horns showed the same changes as the anterior ones.

In the dorsal region the changes were less pronounced; the infiltration was not diffuse, but local, and consisted of lymphocytes, very few plasma cells, and polyblasts.

The glia tissue and white substance were stained with Mann's mixture. The nerve fibers showed normal axones and myelin, but the glia tissue was replaced by so-called ameboid glia and "füll bodies" of Alzheimer. The ameboid transformation of the glia was equally pronounced in both the white and gray matter appearing as homogeneous cell bodies of various sizes and forms, mostly round without any processes, and with a densely stained pycnotic nucleus. Some of the glia cells were preserved, but the glia fibers were transformed in small particles, quadrangular in shape, uniform in appearance, the so-called füll bodies of Alzheimer.

In this case, the parenchymatous changes of the ganglion cells were combined with those of the glia tissue, while the vascular changes were comparatively slight, and those of the white matter totally absent. The picture resembled that of an incomplete myelitis, which, however, could not be diagnosed with certainty because of the preserved condition of the white substance. The ameboid transformation of glia was demonstrated by Alzheimer in many central nerve lesions, caused by severe intoxication or infection, and is quite typical of myelitis. In poliomyelitis, it was described by Walter in one case, and it is probably what Pettersson, Kling, and Wernstedt in their collective report call "hypertrophied glia cells," and Leyden[14] described as "epitheloid" cells.

Case IV.—Boy, 7 years, took suddenly ill, September 24, 1916, at about 2 A.M. with severe headache and vomiting. He was seen by me seven hours later, when he had a temperature of 102°. He showed a normal mentality, was oriented, had no paralysis, no cerebral nerve lesions, no Kernig or Brudzinsky, no neck rigidity. The reflexes were present. A couple of hours later he became worse; the temperature rose to 104°; the headache and vomiting increased in severity; he became apathetic, and had complete aphasia. Slight clonic twitchings appeared in the extremities, but no paralysis or neck rigidity or Kernig was present. The boy died on the way to the hospital at about 1 P.M., *i.e.* eleven hours after the onset of the disease which started, as I said, suddenly without any prodromes.

The postmortem was done by Dr. Le Count, and only the brain and the upper portion of the cervical region of the spinal cord were allowed to be examined. Upon opening the skull there was a marked bulging of the brain, which appeared very edematous and without any particular changes in the membranes.

The microscopical examination of the spinal cord showed: dilated spinal canal, moderate hyperemia of the capillaries, no perivascular infiltration, no neuronophagic phenomena, but the majority of the ganglion cells were slightly swollen (methods: Nissl and Pappenheim's stain, Methyl green-pyronin). The brain was examined with the usual methods (Nissl, Mann, Bielshowsky). The pia was infiltrated, the vessels were dilated and hyperemic. The majority of the ganglion cells were found normal in size and shape, but they frequently showed a pronounced neuronophagia, especially in the deeper layers of the cortex. The neuronophags were exclusively glia cells. Some ganglion cells were broken up, showed mere fragments, and some appeared cystic. Neuroglia tissue showed dilated mashes, a distinct glia reticulum which was especially marked on Mann specimens. In some areas, as the frontal, there was an enormous number of vessels present, the entire visual field having been covered with dilated and hyperemic capillaries which were as numerous as the ganglion cells. The marked glia reticulum, the excessive vascularization, the hyperemia and infiltration of the pia, the neuronophagia, all confined to the brain tissus, indicated an acute meningoencephalitis, while the spinal cord changes were very mild.

The course of the disease in this case was so rapid that a detailed clinical examination could not be done. The spinal puncture done by Dr. Le Count on the cadaver revealed a clear fluid in which Dr. G. Mathers found the gram positive cocci, which he himself, Nuzum, Herzog, Rosenow, and others consider typical for poliomyelitis.

We must, therefore, diagnose this case as a poliomyelitis with its localization in the brain tissue, or as an encephalitis of poliomyelitic origin. The pathological picture did not differ from other forms of encephalitis produced, for instance, by influenza, and without the bacteriological examination it would have been difficult to classify the type of encephalitis in this case.

Aside from its pathological, viz., bacteriological importance, this case also shows some clinical peculiarities. It resembles those cases frequently occurring in private practice, some of which I described some time ago, and which resemble the acute hemorrhagic non-suppurative forms of encephalitis.[15] They run a very rapid course, sometimes but a few hours, and usually die. If they do recover they show signs of permanent brain lesion, as spastic paralysis of one limb or half of the body, aphasia, visual or auditory disturbances, epileptiform convulsions, etc. Cases of this kind used to be diagnosed as encephalitis, bulbar myelitis, encephalo-bulbomyelitis, etc., and their most common etiology was looked for in some infection, as influenza, or intoxication.

There is no doubt, as Strümpell[16] suggested long ago, and as Medin,[17] Harbitz and Scheel and Wickman pointed out later, that these various

cerebral lesions are nothing but a poliomyelitis with cerebral localization, a cerebral poliomyelitis, as it were. Definite proofs, proofs based on pathology and bacteriology, however, were lacking, the only case, that of Harbitz and Scheel (Case XVII of their series), having been observed in an adult, not in a child, while this case of mine furnishes pathological and bacteriological evidence of the correctness of Strümpell's view.

From the short review of these four cases we may form some conclusions as to the possible pathological changes in human poliomyelitis. These changes I could demonstrate in the meninges, in the vessels, in the ganglion cells, in the nerve fibers of the white substance, and finally in the glia tissue. In other words, the histopathological changes in human poliomyelitis may be confined to every tissue that makes up the spinal cord, and roughly are classified as *parenchymatous* changes, of the ganglion cells and white substance, and *interstitial* ones (vascular infiltrations and glia changes). The parenchymatous changes were mostly in the ganglion cells, which were found involved in every case, though not to the same extent. In some cases (I and III) they were much more in evidence than in others (Case III), and in Case IV they were very mild (in the spinal cord). The nerve fibers forming the various columns of the spinal cord were less involved. Nowhere were they found broken up in fragments, as is the case in secondary degeneration, nowhere did they show such destructive signs as in myelitis. In short, their involvement was insignificant, much less pronounced than that of the ganglion cells of the anterior horns, while in the marginal areas of the spinal cord they were practically always normal. The vascular changes, as infiltrations with various cells, were present in almost every case, but again in some very much, in others very little. The glia changes were the most inconstant ones, only in two cases (I and III) were they marked, in the form of ameboid glia.

It follows that, aside from meningeal changes, the most significant and constant ones to be found in acute anterior poliomyelitis are those of the ganglion cells of the anterior horns, and vascular infiltrations. The white matter and the glia also may be involved, but much less frequently. It will be of some interest to compare these findings with those in experimental poliomyelitis produced in various animals—monkeys, rabbits, and sheep, and to see what possible conclusions might be drawn in regard to the essential features of the pathology of this disease.

Case V.—A ring tail monkey was injected by Dr. John Nuzum, on September 28, 1916, intracerebrally, with one c.c. of a suspension of five different cultures from human brains and cords of poliomyelitis cases (including those of the first three cases reported above.) Paralysis (flaccid) developed the following day, and death a day later, September 30, 1916.

The post-mortem examination revealed an enormous congestion and round-cell infiltration of the cerebrospinal meninges. The infiltration consisted almost exclusively of lymphocytes. There was also a very marked congestion with an abundance of capillaries in the gray matter of both anterior and posterior horns, and of the brain tissue proper, but it was much more pronounced in the cervical and dorsal regions. In the lumbar region there were also punctate hemorrhages. Ganglion cell changes in the anterior horns of the spinal cord were in some places quite marked, as well as neuronophagia which frequently was represented by marked satellitosis, some ganglion cells having been surrounded by 5 or 6 protoplasm-poor glia cells, while white matter and glia changes were totally absent. Even the vascular changes in the white matter were not marked in some areas (lumbar cord for instance). In the intervertebral ganglion Dr. Nuzum noted, in this animal, marked neuronophagia.

Case VI.—Another monkey (*Macacus rhesus*) received, October 16, 1916, 0.5 c.c. of a subculture, second generation, from the spinal fluid of two human poliomyelitis cases. Paralysis developed a week later, followed by coma and death.

The post-mortem findings were similar to those in the former monkey, but somewhat less pronounced. In addition, the axones showed marked tumefaction with the myelin preserved.

In both of these monkeys the interstitial changes, the hyperemia of the meninges, the infiltration and congestion of the gray matter strongly resembled the same phenomena in human poliomyelitis, but the parenchymatous changes in the ganglion cells and neuronophagia, though present, were comparatively less in evidence, while neuroglia and white matter changes were either totally absent, or were very mild (swollen axones in the second monkey).

Case VII.—One rabbit, No. 3, was injected intraperitoneally with 15 c.c. of a culture from the spinal cord of patient No. 2 of this series, September 9, 1916. Found dead September 27, 1916. Post mortem: Slight hyperemia and cellular infiltration of the meninges and of the gray matter of both horns of the spinal cord. The ganglion cells were usually swollen, some were preserved, and few showed a slight neuronophagia, in the form of satellitosis, viz., abundance of neuroglia cells. The posterior horn cells appeared more frequently involved than those of the anterior horns. The white matter and the glia showed no changes.

Case VIII.—Rabbit No. 21, was injected intraperitoneally, September 15, 1916 with 3 c.c. of a 24 hour culture from a tonsil of a poliomyelitis patient. Paralysis and death set in six days later. Microscopical examination showed quite marked hyperemia of the pia vessels, very mild vascular infiltration; some ganglion cells showed pronounced neuronophagia and were greatly changed. They appeared vacuolated, shrunken, some again were swollen, the dendrites were usually lacking, but the Nissl bodies were mostly well preserved. The white matter showed swollen axones and very slight vascular changes, while the glia was entirely normal.

The histopathological changes in these two rabbits were much less pronounced than in the monkeys, and were principally of the degenerative or parenchymatous variety, *i.e.* the hyperemia and the perivascular infiltration were considerably less in evidence than in monkey poliomyelitis. Yet the parenchymatous changes, though present, were not sufficiently characteristic to permit of a microscopical diagnosis of poliomyelitis, since similar changes can be produced in rabbits by some other virus, dysenteric, for instance, as can be seen from the report of the next two cases.

Case IX.—A young rabbit was injected by Dr. Frank Francis intraperitoneally, October 3, 1916, with a pure culture of Shiga bacilli. Two days later a flaccid paralysis developed in the front legs, followed one day later by flaccid paralysis of the other extremities, and of the respiratory muscles.

Case X.—Another rabbit was similarly injected intraperitoneally, October 7, 1916, and paralysis of all the extremities set in the next day when the animal died.

In the former animal (Case IX.) no particular changes were noticed, except slight hyperemia of the pia and of the vessels of the gray and white matter, while in the second animal, in addition to the vascular there were changes in the ganglion cells. The majority of them appeared swollen, but preserved their Nissl bodies and nucleus which often contained two nucleoli.

Some ganglion cells of both horns were very much disfigured, especially on Mann specimens—they showed numerous vacuoles within their cell bodies, appeared fenestrated, and frequently broken up in fragments surrounded by numerous glia cells. Other ganglion cells showed excavations filled with glia cells (neuronophagia) some of which were of the ameboid type. The posterior horn changes were more in evidence than the anterior ones. The glia of the white substance was without changes.

We find in these two cases some of the features peculiar to poliomyelitis—hyperemia of the vessels of the pia and the gray-white substance, parenchymatous changes in the ganglion cells, also neuronophagia, but perivascular infiltration was totally absent. Neither the hyperemia nor the neuronophagia, nor even the ganglion-cell changes were pronounced to the degree we usually see it in human poliomyelitis, and a diagnosis of the latter in these two cases could hardly be made with certainty. In other words, Shiga bacilli, or dysenteric antitoxin, as proved especially by the excellent work of Lotmar.[18] in certain doses, may produce changes in the central nervous system, which, however, usually have the features of a myelitis.

Sheep poliomyelitis was studied on the central nervous system of five sheep. Three of these were experimented upon by Dr. Maximilian Herzog and two by Dr. John Nuzum.

Case XI.—Sheep No. 1 was injected (Dr. Herzog) intracerebrally October 10, 1916, with an emulsion of three human brains of patients who had died from poliomyelitis, mixed with three cultures obtained from the spinal fluid of various poliomyelitis cases. Paralysis developed six days later followed by death on the seventh day.

Microscopical examination showed marked hyperemia in the pia and dura; adventitial infiltration was present, and consisted of lymphocytes and leucocytes, but was not of frequent occurrence. There was also hyperemia of the vessels and capillaries of the gray matter; the ganglion cells of the spinal cord especially on Mann specimens were greatly vacuolated, disfigured, and partly broken up; neuronophagia was absent, as well as glia and white matter changes. The brain showed dilated and hyperemic vessels with insignificant adventitial infiltration which was to be found only in few sections, in short was exceptional. The glia tissue was cribriform in appearance with dilated pericellular and perivascular spaces. The cortical cells were broken and showed marked neuronophagia, in some sections. The changes in the brain were more marked than in the spinal cord and justified the diagnosis of encephalitis.

Case XII.—Sheep No. 2: Same injection (Dr. Herzog) as in the previous case, but intraperitoneally, October 10, 1916 (2 c.c.) There was but slight weakness noticed, no paralysis. The animal was killed 12 days later. Microscopically there was found an extensive hyperemia of the gray and white matter, hemorrhagic foci in the gray substance of the anterior and posterior horns, tumefaction of some white fibers and of the dendrites of the anterior horn cells. The ganglion cells and the glia tissue were apparently normal.

Case XIII.—Sheep No. 6, inoculated intracerebrally, October 25, by Dr. Herzog, with an emulsion of the brain of sheep No. 1. The animal was very sick for 10 days, developed convulsions and died November 7. For three days she was dragging the left hind limb and could hardly get up. Microscopical examination showed marked hyperemia of the pia-dura and of the gray matter, but a very slight one of the white substance. Perivascular infiltration was totally absent. The ganglion cells mostly appeared swollen with preserved Nissl bodies, and dentrites well stained. Some ganglion cells manifested deep destruction, appeared vacuolated, broken up; neuronophagia was usually slight and inconstant. The white substance also showed changes—myelin was broken up in fragments and scattered over the visual field, but the axones were retained, though swollen. The glia showed deep changes—both in the gray and white matter, it showed the ameboid transformation.

Case XIV.—Sheep, a small lamb, injected intraspinally by Dr. John Nuzum, October 15, 1916, with 2 c.c. of a polyomyelitic, cerebrospinal fluid culture. Two days later flaccid paralysis developed followed by convulsions and death on October 18, 1916. Microscopical examination showed hyperemia and cellular infiltration of the pia and dura all along the spinal cord. The ganglion cells, as a rule, had preserved their size and configuration, though they showed chromatolysis; other cells were shrunken, broken up, and often represented by mere fragments. Many cells, especially on Mann's specimens, were vacuolated. Other ganglion cells were packed with glia cells, and some appeared granular. Small vessels and capillaries were very hyperemic, and showed perivascular infiltration (many plasma cells). The axones were swollen, but the glia tissue was unchanged.

Case XV.—A small lamb was injected intracerebrally by Dr. John Nuzum with 1 c.c. of a spinal fluid culture from a poliomyelitis patient, October 15, 1916. Two days later flaccid paralysis developed followed by death 64 hours after the injection. Microscopical examination showed capillary hemorrhages in the gray and white matter, slightly swollen axones, and no other changes.

Thus the histopathological findings in sheep poliomyelitis are by no means uniform. The last one, Case XV, showed hardly any changes whatever, except hemorrhages in the gray matter; one, Case XII, showed principally infiltrative changes in the presence of very slight degenerative ones, the rest (XI, XIII, and XIV) showed both degenerative and infiltrative changes. The mild changes in Case XII might be attributed to the mode of injection (intraperitoneally), or probably to the slight virulence of the poison, or to the greater resistance of the animal. The general impression of the sheep poliomyelitis is that sheep present less marked anatomical changes than monkeys, yet they are very susceptible to the virus, as successful inoculations usually cause rapid death, the general infection sometimes killing the animal before distinct anatomical changes obtain in the central nervous system.

Comparing the pathological changes in the experimental and human poliomyelitis we can see that the classical signs of the latter, as perivascular infiltration, pia congestion, degenerative or parenchymatous changes in the ganglion cells, neuronophagia, etc., being more or less constant in fatal human poliomyelitis, are not always to be found equally represented in the experimental form. They are more or less frequent in monkeys, but in rabbits principally degenerative changes are to be found, and in sheep, as I said, either may obtain.

I wish again to point out the fact that a definite or *sure* pathological diagnosis of acute anterior poliomyelitis in any of the animals of this series could not be made by any means. A diagnosis of meningomyelitis, or degenerative myelitis, would be quite suggestive and not far from the truth. In fact, the pathology of human poliomyelitis is, according to the majority of investigators, nothing but a myelitis, in view of the marked interstitial changes to be found in every case of a fresh poliomyelitis. Such interstitial changes were noticed by some of the earliest students of this disease, as Roger and Damaschino. They looked upon poliomyelitis as a central myelitis with foci of softening, combined with atrophy of the ganglion cells of the anterior horns. They thus somewhat broadened the famous teaching of Charcot that anterior poliomyelitis is a

primary disease of the ganglion cells of the anterior horns, and is therefore exclusively a parenchymatous, degenerative, not inflammatory, process. The subsequent investigations of Redlich,[19] Wickman, and others practically confirmed the correctness of the opinion of Roger and Damaschino, that Charcot's teaching, though basically correct, must be somewhat broadened, at least for the majority of cases. Yet Rissler and others insist on the primary atrophy of the anterior horn cells as being the basis of poliomyelitis, and the vascular changes are looked upon merely as secondary phenomena. In opposition to this teaching, Goldscheider[20] proclaimed just the opposite views—vascular changes are the primary, the parenchymatous, *i.e.* ganglion-cell, changes are the secondary ones.

Since the experimental cases demonstrate that in some animals (rabbits) the parenchymatous, in others (monkeys) the interstitial (or infiltration) changes prevail, and in sheep, again, either form may obtain, we must admit that neither of these teachings is absolutely correct, that both parenchymatous and interstitial changes are independent phenomena, caused by the same virus.

THE EFFECTS OF CIVILIZATION ON THE MORBIDITY AND MORTALITY OF TUBERCULOSIS.*

BY S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

CAPTAIN, MEDICAL RESERVE CORPS, U. S. ARMY; PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY, AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; SENIOR VISITING PHYSICIAN TO THE RIVERSIDE HOSPITAL-SANATORIUM FOR THE CONSUMPTIVE POOR OF THE HEALTH DEPARTMENT OF THE CITY OF NEW YORK.

KRAFT-EBING once said that civilization and syphilization go hand in hand. I am tempted to say the same of tuberculosis, for civilization and tuberculization do seem indeed to go also hand in hand. Before our Indians came in touch with civilization tuberculosis was unknown among them; now they are dying fast from this disease. The Negro, prior to his tasting the freedom of so-called civilization, was virtually free from tuberculosis; now this race presents the greatest morbidity and mortality rate from this same malady.

There is nevertheless a great difference between tuberculosis and syphilis in their relation to civilization. It is today universally admitted that the vast majority of the people who have lived for generations in cities and towns have at some time had a tuberculous infection. Modern pathological science corroborates this, for the majority of individuals who have died from accidents or other diseases than tuberculosis have shown, when their bodies were autopsied and all organs macroscopically and microscopically examined, that they had had a tuberculous infection at one time or other in their lives. Many authorities maintain that this infection even conveys a certain immunity to future infections and that only when a new invasion of tuberculosis germs becomes overwhelming, or when privation, malnutrition, exposure, intemperance, lack of air and sunlight, or overwork undermine the natural resistance, does the latent tuberculous focus which was the result of the primary infection, suddenly become active and we have a tuberculous disease.

Although tuberculosis was known and quite prevalent in antiquity and Hippocrates has given us an admirable description of the symptoms of the disease, which he called phthisis, it has become the typical disease of the masses more particularly during the last and present centuries when the very large migration from country to city took place and the various industries became established. Factory hygiene was and is yet in many instances deplorable. Long hours of work and congested life in unsanitary tenements cause a deterioration of both physical and moral stamina among a large propor-

*Read before the American Academy of Medicine, at its forty-second Annual Meeting in New York City, June 4, 1917.

tion of the urbane population. The best example in our own country is perhaps shown by the Italian and Irish immigration. The Italian laborer prior to his coming to this country has usually been engaged in farm work, and owing to the mildness of the Italian climate he has lived much in the open air. When he comes to this country he submits himself to contract labor of the hardest kind and lives in the most unsanitary way in crowded and congested tenement houses. A large number of the Irish population offers the same problem and as a result the tuberculosis morbidity and mortality of both the Italian and Irish population is very great.

To all this must be added intemperance, that is to say excessive indulgence in strong alcoholic drinks which, with all its dire consequences, is a symptom of so-called civilization. In my work as physician in charge of a large tuberculosis service in the largest city of our country, I have found alcoholism one of the most prevalent and most serious predisposing factors of tuberculous disease, and we have a large population of men and women who contract tuberculosis anew or develop an active disease from a latent tuberculous infection because of bad hygiene, malnutrition, intemperance, syphilis, and other vices of civilization.

What progeny can we expect from parents who are tuberculous? What chances have the children of such parents? Before giving you an answer to the sociological aspect of the question, permit me to say that whether we believe in direct hereditary tuberculous transmission or not there is no doubt that if a tuberculous mother is ill enough to secrete tuberculous toxins, these toxins will effect the cell-life of the fetus with the result that a child will be born with a physiological poverty and a strong predisposition to tuberculosis. The chances that this child will become tuberculous by postnatal infection are so numerous and so well known that I do not deem it necessary to enumerate them here. The more close and more prolonged is the contact of the infant with its tuberculous mother, the more surely will the child become infected. If the father is tuberculous and the mother must do the work, while the family increases in number as is usually the case, we have one of the sociological aspects of tuberculosis and civilization.

As an example of this condition I do not believe I can do better than to cite a pathetic incident incorporated in an address on Preventive Medicine and Birth Control, which I had the honor to deliver last March upon invitation before the New York Society of Medical Jurisprudence. The Hon. Judge William H. Wadhams of the Court of General Sessions had freed upon a suspended sentence a woman accused of burglary, and his own words tell the story: "The woman's tuberculous husband is not permitted by the authorities to work because of his being ill with tuberculosis. It would be dangerous for him to work on children's garments. It might spread the consumption to the innocents. There is a law against that. As a result of this law the husband has had no work for four years. Nevertheless, he goes on producing children who have very little chance under the conditions to be anything but tuberculous, and themselves growing up, repeat the process with society. There is no law against that. But we have not only no birth regulation in such cases, but if information is given with respect to birth regulation people are brought before the bar of justice for it. There is a law they violate. The question is whether we have the most intelligent law on this subject we might have. These matters are regulated better in some of the old countries, particularly in Holland, than they are in this country. I believe we are living in an age of ignorance, which at some future time will be looked upon aghast. So here we have a family increasing in number, with a tuberculous husband, with a woman with a child at her breast, with other small children at her skirts, and no money. There is a report which I have from the Charity Society showing that the defendant, this woman, had to have assistance from time to time to keep from actual starvation, and in order to give her family bread she steals. I will not send her to jail. Sentence is suspended."

Had I the time, I could tell you any number of similar stories out of my own practice. In my work in the tenements and overcrowded hospitals I have again and again witnessed the sufferings of many a tuberculous mother whom I could not help because it was too late to prevent. The despair of the poor, frail creature at the prospect of another inevitable confinement, the likelihood of her early decease as a result of this newly added pregnancy, the thought of her other children who would be deprived of a mother's care at ages when they need it most, and later the sight of a puny babe destined to disease, poverty, and misery, opened my eyes to the utter immorality of thoughtless procreation, not only of the tuberculous, but of all the physically and mentally diseased and impoverished. Yet there are some people who have criticized men like Drs. Biggs, Jacobi, Holt, Reed, Professor Sprague and many others of equal prominence and your humble servant because of our belief in birth control to prevent the thoughtless procreation of the physically and mentally unfit.

In my research work for a paper on the "Period of Life at which Infection from Tuberculosis Occurs Most Frequently,"* I discovered that the age at which a tuberculous infection contracted in infancy or childhood usually becomes active is at or after 15 years. I can only account for this by the prevalence of child labor causing an excessive physical strain on the delicate growing organism which loses its natural resistance to a new invasion of the bacilli or the awakening of a latent infection. Child labor, which is still the curse of our nation in many States, is a factor of our modern civilization largely responsible for the high morbidity and mortality rate from tuberculosis among our young people, particularly at the period of adolescence.

Child labor, unfortunately, is not confined to factory, cannery, or workshop, it is also met with in the homes of the poor and even the middle classes. The homes of the poor are often made into sweatshops and children frequently of tender age are forced to participate in the making of artificial flowers or the sewing of garments for many hours,

*"The Period of Life at Which Infection from Tuberculosis Occurs Most Frequently. How May We Diminish the Frequency of Those Infections and Prevent Them from Becoming Tuberculous Diseases?"—MEDICAL RECORD, January 8, 1916.

sometimes late into the night. In some homes, the older children, particularly the girls, are worn out by being forced to assume the rôle of little mothers and caring for the younger children in the absence of the parents or when there are too many little ones to be taken care of otherwise. Boys are often forced to attend to chores beyond their physical endurance, and this practice is by no means confined to the families of the poor. I also venture to say that the curricula of many of our schools resemble child labor, particularly when they demand a great deal of home work, and they have the same effects inasmuch as they are certainly detrimental to the physical development of the growing organism of the child.

Modern civilization with all its industrial advances has thus far, with a few exceptions, neglected the physical examination of apprentices to trade or commerce so that the tuberculous or those predisposed to tuberculosis might be weeded out and referred to institutions for treatment, and not constitute later on sources of infection for their fellow workers.

There is also much tuberculosis among the rural population in both children and adults which is probably due not so much to overwork as to the unhygienic way of living in home and at school. Many country school houses are notoriously unhygienic; heating and ventilation are of the crudest kind, and country housewives are noted for excluding the good country air by day and by night and saving it for the city visitors in summer.

Insufficient ventilation in factories, workshops, stores, and offices, not excluding even our federal institutions, schools, and colleges, must be considered one of the most important indirect causes of tuberculosis in our present state of civilization. Insufficient knowledge on the part of many housewives of how to cook well and economically and at the same time provide nutritious food, is one deplorable cause of underfeeding which in turn predisposes to tuberculosis.

It is particularly the school child of the poorer classes who suffers from malnutrition. It has been shown that of the 1,000,000 school children attending the public and parochial schools of this great city of New York, 160,000 are underfed. Here is an opportunity for practical philanthropy to provide nutritious midday luncheons at a minimum price for these children, not only while school is in session but also during the vacation.

Another reason for the large morbidity and mortality from tuberculosis among the children of the poor as well as of the more well-to-do classes is the inability or disinclination of many mothers to giving the breast to their infants. The poor working woman employed in factory or workshop, often not well nourished herself, has to snatch away a few moments from her daily task to give her child the breast. It finally becomes too great a burden and the child is no longer brought to the factory, but fed artificially by an older child or kindly neighbor. The society woman is occupied with what she thinks more important matters which her rank and standing demand, so the poor rich baby is as badly off in this respect as the poor poor baby. So-called civilization prevents both mothers from performing the most important duty which nature has imposed upon them. Physicians who have paid any attention to child development and subsequent diseases during adolescence will bear me out when I say that the breast-fed child, as a rule, will withstand the invasion of pathogenic germs much more readily than the artificially fed infant. In countries where military conscription is in vogue it has been found that many more of the candidates who have a history of having been breast-fed infants are fit for military service.

Many occupations, trades, and industries of today involve the inhalation of vegetable and mineral dust which irritates the mucous membranes of the respiratory organs and offer suitable culture mediums for the ubiquitous tubercle bacillus.

Dust collectors and the best possible factory sanitation are the only means to do away with this indirect source of tuberculosis, but not only the laborers in their factories but the ordinary citizen is often exposed for days and days to the inhalation of all kinds of dust. The tearing down of houses which is a daily feature of nearly all of the great cities, is productive of any amount of dust of a most irritating kind. An equally annoying and almost as dangerous practice is the old fashioned way of beating carpets. The contractors undertaking the wrecking of a house should be obliged to wet thoroughly the walls, ceiling, and floors before beginning the wrecking operation, so as to reduce the dust nuisance to a minimum. Carpet beating should not be permitted in a densely populated community when pneumatic cleaning by the suction process can be done so much more hygienically. Let us also hope that this modern way of collecting the dust from within the houses will, in the near future, be made applicable to our methods of street cleaning.

A penalty should be imposed upon any one who intentionally or carelessly places bottles or broken glass in the streets. Leaving aside the danger from cuts, when broken glass is ground to powder by the traffic it certainly adds to the irritating quality of the dust in the city air we must breathe. Collecting ashes and garbage should be done with the aid of two sets of receptacles with tightly fitting covers so that the air may neither be polluted by ash dust nor offending smells from garbage. Whenever possible, the use of hard coal should be made obligatory, and where soft coal must be burned some of the many and constantly improving smoke consumers should be installed. They will not only prove a great hygienic advantage to the citizens, but also an economic advantage to the consumer.

The conditions of modern industries requiring that many workers shall congregate in one place to perform their work, make a periodical examination of all laborers in our modern factories a necessity. According to the statistics which I have been able to gather, the age at which tuberculosis is diagnosed and apparently contracted most frequently in adult life is between 20 and 35 years. It is because the periodical examination of laborers for tuberculosis is neglected in most of our modern industries and the early cases not recognized nor treated that tuberculosis has become most prevalent at that period of the life of the laborer.

All this shows that with the increase of population and consequent congestion the very conditions which modern civilization has created, with the object of widening the scope of life and making

man master of the earth he inhabits, are such as to foster the spread of many diseases which were not prevalent in a more natural condition of life. But in bending nature to his will and uses, man must not forget that he himself is a part of that same nature. Thus, civilization must go one step further and improve the conditions which itself has caused to exist. Thus shall it indeed be worth of the name.

Among the first things, we must have a more intensive antituberculosis education among the masses, including the Indian and Negro races. We must teach tuberculous parents not to procreate while actively diseased; encourage breast feeding; do away with child labor as a curse of the nation; replace the old type of school curricula by a modified Gary system, including more open air classes;* improve factory hygiene and prevent sweatshop labors. We must institute sanitary supervision of tenement and lodging houses; encourage the migration from city to country by making farm life more profitable and attractive through wise statesmanship and philanthropy; and last but not least, we must have compulsory insurance for all working people, including maternity insurance and insurance for tuberculosis.

Our present war is justified because it is a war for liberty and true civilization, and it is my firm conviction that it was a false idea of civilization which is responsible for this world catastrophe the magnitude of which in its relation to tuberculosis can hardly be realized at this time. Only a faint idea of the terrible results on the increase of tuberculosis in the civilized world during the past three years may be gained from the fact that in one of the warring countries alone, in brave and beautiful France, not less than 150,000 soldiers have had to be returned from the fighting line because they had developed an active tuberculosis which incapacitated them for further service. As a result of the privation and suffering which this terrible war has entailed, there are now no less than 400,000 to 500,000 active open tuberculosis cases in France alone. In Poland, Serbia, Roumania, and in the other warring countries conditions are identical if not worse. The United States, its government and its people must prepare for similar calamities, or rather seek to prevent them by wisely husbanding our food supply, our supply of coal, wool, and cotton, preventing speculation in the necessities of life and maintaining a high standard for housing the masses. If want of any of these necessities arises, it is sure to be followed by an increase of tuberculosis. But above all else, we must keep up our vigilance against the dissemination of the great white plague. We must increase our facilities for the prevention of tuberculosis and for the care of the tuberculous; increase our hospital and sanatorium accommodation; increase the number of clinics for early diagnosis and the care of ambulant cases; insist on more open air schools or at least open air classes; and last but not least, I say it again, keep up our educational propaganda.

In addition, we must at this time prepare ample sanatorium and hospital accommodations not only for our own soldiers who may return to us tuberculous, but also for prisoners from the central powers who may come to us afflicted with tuberculosis. Lastly, we should consider all the young men who are rejected from military service because of physical weakness, particularly those with a slightly incipient tuberculosis or those who are considered arrested cases. They should be given an opportunity to enter a sort of reserve army to be mobilized for agricultural work and other outdoor industries that would be beneficial to them in building up a weak constitution. If such agricultural and outdoor industries, most urgently needed at this time, could be organized on a military basis and the men allowed a uniform similar to that worn by our Home Defense League, I have reason to believe that many would gladly avail themselves of this opportunity to be of service. By the formation of such an industrial army these young men will be helped physically and morally and would render an invaluable service to the country at large by the increase of its agricultural, horticultural, and other products. Medical officers should, of course, form a part of these industrial units so that they could watch over the health of the men composing the colonies and even regulate the hours of work so that relapses of the former tuberculous patient or the breaking down of the incipient invalid may be avoided. I have reason to believe that after six to twelve months training in such a colony perhaps quite a number of young men would graduate therefrom physically and morally well and fit to enter the regular army.

Civilization, such as it is, is doubtlessly responsible for much if not for all the tuberculosis in existence. But there is still hope, for this same civilization has also awakened in man his sense of duty in the combat against the great white plague. In nearly all countries of Europe and America antituberculosis work has been in progress and our own country has not been behind. In Europe the present war has not only, as already pointed out, increased the fearful morbidity and mortality of the disease, but it has also stopped all educational propaganda and all municipal and state philanthropic enterprises which were directed against tuberculous invasion. Let us hope that when the strife will at last be ended there will be a reawakening throughout the civilized world and a renewed activity of all the agencies which have been heretofore so helpful in the antituberculosis crusade. Civilization, such as it should be, can do away with this as well as other diseases of the masses. Tuberculosis can be prevented, it can be cured, it can even be eradicated by true civilization; but to be truly civilized, we must replace ignorance and superstition by education and enlightenment, social injustice by social justice, selfishness and greed by love and generosity, egotism by altruism. In short, we must realize that health and happiness and peace cannot be truly enjoyed if they are the property of a few, for true civilization in its divine interpretation means a happier, healthier humanity for all peoples and nations and peace and good will on earth.

16 West Ninety-fifth Street.

*I should like to see the Gary system so modified that there should be given at least one-half to three-quarters of an hour of relaxation to all the children and teachers, preferably in the middle of the day.

Silent Peritonitis.—Minet reported three cases of almost sudden death in the absence of symptoms. Autopsy revealed the presence of acute peritonitis.—*La Presse Médicale.*

NON-SPECIFIC PROTEIN TREATMENT OF INOPERABLE CANCER.

By S. P. BEEBE, M.D.,
AND
H. S. WILLIAMS, M.D.,
NEW YORK.

THE writers have called attention in previous publications to a method of treating inoperable cancer by injections of extracts prepared from a group of plant substances. At the time of the first publication the work had not progressed to such a degree that it was possible to offer a satisfactory theoretical explanation as to why the observed effects occurred. During the last two years both the experimental and clinical work have brought important new facts and observations so that it is now possible to state what appears to be a possible hypothesis for the therapeutic action noted and to correlate the results obtained with the work of other students in this field.

It is unnecessary to repeat the origin of the writers' interest in this method. The earlier work was, in many respects, unsatisfactory and difficult. It involved the use of a therapeutic agent which was prepared from a series of herbs that are little used in medicine and never before by the method proposed. Moreover the method seemed to have no relation to the accepted theories regarding cancer or the previous methods of treatment. "Essentially, however, the material used for injection was a saline extract rich in a variety of vegetable proteins, organic salts, extractive materials, and contained some chlorophyll, chromophyll, and lipoids in an emulsified condition." It was observed very early in the course of these experiments that injections of the extract produced characteristic protein reactions and as the work progressed it was this factor which more and more attracted attention. The other substances in the extract were believed to be not only useless, but disadvantageous and the experience of the last year has demonstrated such to be the case. Moreover, if this is a protein reaction it is inconceivable that the plant substances at the basis of the original extract are the only ones which afford a suitable type of protein for this purpose. Our experience of the last year indeed demonstrates such to be the fact. The present paper is a brief outline of the progress from an extract prepared from a congeries of herbs, many of which we know contributed no protein, and contained irritating substances to standardized solutions of proteins prepared by simple methods from common seeds.

It is unnecessary and space will not permit outlining all of the experiments made with the original mixture to locate the essential factor in the extract, nor is it necessary to rehearse at this time the long series of experiments made with proteins prepared by various methods from other common seeds. The result of this work is that during the last year we have selected a method of preparation that is simple in execution and gives a protein solution readily sterilized and standardized, that is non-irritating on injection, in suitable doses causes no disturbing general reaction, is comparatively cheap and from the therapeutic standpoint is effective in stimulating the blood changes which we believe to be the basis of its action. We have experimented with a variety of seeds but most of the work has been done with proteins obtained from alfalfa meal, alfalfa seed, sweet clover seed, hemp seed, rape seed, and millet seed. The proteins vary somewhat in their action and we have found the proteins from alfalfa meal (the whole plant ground to a fine powder), alfalfa seed, and millet seed the most satisfactory. The method of preparation is extremely simple.

Fifty grams of the seed meal are placed in a flask with a reflux condenser; 1,000 c.c. of distilled water and 40 c.c. of 10 per cent. hydrochloric acid are added. The mixture is boiled for three hours and the coarser particles strained out through gauze. The filtrate is concentrated to 200 c.c. approximately and the excess of acid neutralized with 10 per cent. solution of sodium hydroxide. It will be found that an abundant precipitate of acid albumin forms when the extract is neutral to litmus. It is best to add sufficient sodium hydroxide to get a very faint alkaline reaction to litmus. A portion of the first precipitate formed will redissolve under these circumstances. The faintly alkaline solution is filtered and the filtrate concentrated to such a point that its nitrogen content is 0.3 per cent., as measured by a Kjeldahl determination. The concentration needed for this purpose varies somewhat in each case but the final bulk of the standardized protein solution from this amount of material is about 100 c.c. If the reaction is very faintly alkaline the solution may readily be sterilized by boiling. The solution contains alkali albumin, proteoses, and a small quantity of peptone. It is a most excellent culture medium for a variety of organisms and ought to find extensive use in bacteriological laboratories for this purpose, but for therapeutic use the only safe way to preserve it is to seal the solution in small glass ampoules which are then sterilized by the discontinuous method.

The method outlined above applies to both millet seed and alfalfa seed. For the alfalfa meal extract it is best to add only 10 c.c. of the 10 per cent. hydrochloric acid and boil for one-half an hour. Otherwise the same procedure is followed as for the seeds.

The saline extract of alfalfa seed or millet seed prepared by simple extraction in the cold and containing native heat coagulable proteins is quite toxic to the human subject and seems in no way to be more effective than the solutions of partially hydrolyzed proteins prepared by the method outlined above.

All of our recent work has been done with such proteins and the method has the advantage of giving a stable sterile solution, non-irritating, and comparatively non-toxic in character. The dose varies somewhat with each patient. As a rule we begin with a dose of 5 to 8 minims and increase gradually to 15 to 25 minims. The injectons are made subcutaneously with an ordinary hypodermic syringe. Injections are made at varying intervals, in some cases daily, and in others at two or three day intervals. As a rule we see no advantage in giving the injections intravenously nor is it necessary to cause the severe constitutional reactions accompanied by chill, fever, nausea, vomiting, herpes, labialis, etc., that have been described in some of the articles

on non-specific protein administration. The partially hydrolyzed protein which results from the method described does not cause the marked anaphylactic reactions which have been observed to follow the administration of the native proteins obtained from the same seeds, and that were occasionally noted in giving the original extract. This is what might be expected from the work of Osborne and Wells.

We believe that the beneficial therapeutic effects which have been noted are a consequence of the marked blood changes occasioned by the protein injections. These changes are briefly: increase in the hemoglobin and red cell count; marked improvement in the shape, size, and staining qualities of the red cells; marked reduction in the total white count in those cases showing a leucocytosis; relative reduction in the percentage of polynuclear leucocytes in some cases diminishing to as low as 40 to 45 per cent. in a total count of 7000 to 8000; marked relative increase in the large mononuclear leucocytes reaching not infrequently a percentage of 30 to 35 in a normal total count; increase in the size and improvement in the staining qualities of the large mononuclears. These changes are definite in character, are produced gradually over a period of some weeks or months, and persist for a long time; in some cases noted for a period of nearly two years, and continue for months after the injections are either stopped altogether or are given at long intervals. These blood changes are not immediate consequences of a single injection, like a marked polynuclear leucocytosis following the administration of a bacterial vaccine, but are gradual changes developing during a period of weeks or months.

We have observed that those patients showing the most marked clinical improvement show also the most decided blood changes. Space will not permit a discussion of the mechanism by which such blood changes are operative in producing the therapeutic benefit. These changes have been noted by other investigators, notably Vaughan, after the administration of cancer vaccines or leucocyte extract, and by Klinger following the injection of organ autolysotes, though not to the same degree as we have observed to follow the injection of non-specific vegetable proteins.

The degree of therapeutic benefit that may be expected in a given case cannot be predicted in advance. The patients subjected to this treatment up to the present time have been for the most part the far advanced inoperable cases beyond the reach of accepted methods of treatment. The following outline of results is based upon the personal treatment of more than 500 patients and upon the results reported by correspondence from other physicians on approximately 2,500 additional patients. Space does not permit details of case histories but a wide variety of types of malignant growths are included in the treated cases. In a small percentage, approximately 20 per cent., no benefit either subjectively or objectively was observed. With the remainder the improvement noted was evidenced by the following changes:

1. Diminution in pain. Morphine can be either entirely eliminated or reduced to comparatively small doses.

2. Foul discharges associated with ulcerating surfaces and infected growths, notably the uterus, are very markedly modified for the better.

3. Improvement in appetite, gain in weight, diminution or complete disappearance of the cachexia and anemia.

4. Diminution or complete cessation of bleeding from ulcerating growths.

5. Diminution in the rate of growth or its complete cessation followed by regression; in some instances amounting to complete absorption and seeming recovery.

A variety of biological agents have been suggested and used during recent years in the treatment of inoperable cancer and in every case the therapeutic agent, regardless of the theory upon which it was based has been some form of protein. Among these are Coley's toxins, various types of animal serums, specific or otherwise; various types of bacterial vaccines; a variety of vaccines prepared from cancer tissue such as those proposed by Coca and Gilman, the Vaughan residue, the Fichera emulsion, Klinger's autolysates, numerous fluids from serous cavities of either normal or cancer subjects, notably Hodenpyl's ascitic fluid, normal human blood serum, hydrocele fluid, spermatocele fluid, pleuritic transudate; extracts of various of the ductless glands; Gwyer's X substance prepared from a variety of organs but preferably from the thymus; digestive ferments such as trypsin and amylopsin suggested by Beard. All of these agents have had active partisans and there is considerable evidence to show that all of them have to some degree produced beneficial results in a certain number of cases, and some of them are still employed and championed by a number of physicians. Is it not probable that such beneficial action as they have shown is occasioned by the reaction to the injection of a foreign protein?

The treatment of the inoperable cancer patient by injections of vegetable protein is not suggested to displace present accepted methods of therapeutics. It is an addition which permits varying degrees of relief to patients for whom other methods of treatment offer little or nothing. The injections must be continued over long periods of time. We have patients in good general physical condition who have been under treatment for two years and have received as many as 250 injections in that time. To get the best results we believe that it is necessary to change occasionally the type of protein administered.

The method of preparing the protein as outlined in this paper is extremely simple and can be carried out by any physician with comparatively small laboratory facilities. The equipment afforded by the clinical laboratories of most hospitals are adequate for this purpose. The protein so prepared is suitable not only for the treatment of the inoperable cancer patient but also for other conditions in which it is desired to administer this form of therapy. It is our belief that better results will be produced by giving the proteins in small doses subcutaneously over considerable periods of time and without provoking the decided and unpleasant general reactions that follow larger doses given intravenously.

104 East Fortieth Street.

ALCOHOLISM IN RELATION TO EPILEPTOID STATES AND EPILEPSY.*

By ALFRED GORDON, M.D.,

PHILADELPHIA.

The not infrequent occurrence of epileptoid attacks in the course of alcoholism points to a certain relationship between the two conditions. Alcoholism, like other intoxications, such as saturnism and ergotism may be accompanied by sudden attacks of *cramp-like* sensations. The suddenness of appearance and disappearance of the latter places them logically among the epileptoid attacks. In one of such patients in my series, sudden violent muscular contractions would occur in the calf muscles of the right leg at irregular intervals lasting but a few seconds, after which he would feel exhausted. Another chronic alcoholic had similar attacks in the left side of his face. He thus describes the seizure: suddenly he would feel nauseated, a cramp-like sensation would be felt in the muscles of the face on the left side but would disappear at once, then he felt drowsy for 10 or 15 minutes. The epileptoid character of such a condition is self-evident.

Vertiginous attacks present another variety which may occur in chronic alcoholic intoxication.

A patient, aged 30, who was addicted to alcohol for ten years, by consuming daily several glasses of brandy had on occasions of excess attacks of delirium tremens. Within the last two years he developed attacks of vertigo. The latter did not occur on any special physical effort, but might take place without any premonitory sign when the patient, being a reporter for a local newspaper, was quietly engaged in writing his articles for the editor. An attack consisted of a sense of falling off the chair so that he actually had to hold on to the table, and of the objects before him being displaced. The suddenness of the onset, the extremely brief duration, the sudden termination of the attack were all indicative of its epileptoid character in the form of petit mal.

In another patient an analogous attack occurred only while walking. He was 39 years of age, a banking clerk by occupation. His alcoholism dates from the age of 22 and commenced at the time of the death of his mother. At first he drank very heavily and continuously for a period of two months. Subsequently he developed a frequent desire for periodic intoxication. Every three or four weeks he would be taken with an irresistible desire to isolate himself and abandon himself to drink. The attack lasted from two to six days. In the intervals he suffered from vertiginous attacks only during locomotion on the street. At no time did he have these attacks during his work or while in a sitting posture. The attacks were so brief, appeared and disappeared so abruptly that they left no doubt as to their epileptoid nature.

Psychic states of a sudden onset without motor manifestations may occur in alcoholism. Besides acute hallucinosis, Korsakoff's psychosis, and delirium tremens, all characteristic of alcoholism, there are also varieties of psychic states which have a strong resemblance to the psychic states of genuine epilepsy. We find in the former the same sudden disturbance of consciousness and amnesia concerning the disorder as in the latter. Not infrequently the disturbance is of an explosive character and of such a nature that it is totally foreign to the individual's disposition.

A middle-aged woman who for years had used alcohol and sometimes to excess, was subject in the intervals to sudden attacks of unusual irritability. Ordinarily of a most amiable and gentle disposition she would suddenly be seized with an outbreak of sudden excitement and anger, employ the most abusive vocabulary toward her children and husband for whom she usually had the greatest admiration and respect. After the attack was over she had a most hazy recollection of it and, when reminded, she would shed tears and in the most pathetic manner express her regrets to those whom she happened to attack in her pathological state.

The disturbance of the psyche in alcoholic individuals may manifest itself in a manner somewhat different from the one just described, but nevertheless essentially analogous.

A man of 40, electrician by occupation, chronic alcoholic, with a history of delirium tremens on several occasions, presented short periods of *second personality*. He would suddenly imagine and feel that some one within himself interfered with his work. In adjusting and connecting electric wires he had to discontinue his work a number of times, as every time he placed the wires in their proper position "an invisible force" would move his hands in an opposite direction. He had no visual hallucinations as he did not see the foreign force, but, he said, he felt as if some one actually moved, materially speaking, his hands away from the wires. This was done so quickly by "someone in himself" that he had no time to resist. He frequently asked for explanation of such occurrences; while he could not understand them he nevertheless realized their existence. They were so tormenting to him that for hours he had to discontinue his work. The other interesting feature about these phenomena is their occurrence shortly after his recovery from the periodic alcoholic excesses. The longer were the intervals free from drink, the longer was the psychic state of the second personality absent.

Another patient, a woman of 32, of high intellectual attainments, authoress and musician, became addicted to the use of alcohol following a strong disappointment. She drank periodically and in the intervals she presented not infrequently the following attacks: Suddenly she would commence to mutter unintelligible words, have a vacant look, apparently not being able to recognize surroundings, take a few steps in an aimless direction; then she would sit down and the attack was over. The entire picture was that of a Dämmerzustand which may resemble a hysterical state, but it was not, in view of the brevity of the attack and because of the total amnesia of the event. Besides, there were no hysterical stigmata.

The three observations just cited are examples of variations of pathological psychic states which by the mode of onset and of termination, by the amnesia following each individual attack, by the brevity of the duration and the patient's behavior during the attack—are all highly suggestive of epileptoid manifestations and could be considered as equivalent of the latter.

The next important problem in the subject under discussion is the occurrence and relationship of alcoholic intoxication and *epilepsy* proper. If the essential feature of the latter is found in the convulsive seizures, several possibilities are to be considered. First, epileptic convulsions may occur in acute alcoholism in individuals otherwise sober. Here we meet with two groups of cases. In one we find individuals free from any pathological hereditary predisposition and in the other individuals who have had attacks of epilepsy. Second, epilepsy may occur in the course of chronic alcoholic intoxication either à propos of a sudden excess or else without the latter. Here also one must bear in mind the possibility of personal or hereditary morbid predisposition or the existence of epilepsy long before the alcoholism.

*Read by invitation at the annual meeting of the National Association for the Study of Epilepsy, held at Skillman, N. J., May 28 and 29, 1917.

In the first of these groups of cases the epileptic attacks are merely accidental provided the individual was not subject to convulsive seizures prior to his intoxication. While cases like these are not frequent, nevertheless they have been observed and the logical conclusion is that when an individual habitually free from epilepsy becomes intoxicated and while under the influence of alcohol develops convulsive seizures in all respects identical with those encountered in genuine epilepsy—alcohol must be classified as an epileptogenous agent. Moreover it has also been noticed that when in such cases total removal of acute intoxication is strictly observed, no recurrence of convulsive seizures takes place. In one of my patients, a young man of 29, a convulsive attack occurred in the course of each debauch. He was removed to a sanatorium where he was kept under observation for several months, free from alcohol and there was no recurrence of the seizures. A year later he resumed the use of alcohol and again was there a return of convulsive attacks. Although in this case there was no previous personal history of epilepsy or of any other nervous disorder, nevertheless there seemed to be a special predisposition to an epileptogenous effect of alcohol. Thus the direct relationship of alcohol and epilepsy appeared to be firmly established. Another patient, male of 23, has had epilepsy since the age of 7. It was of both major and minor types. When he reached the age of 18 the convulsive attacks diminished greatly in intensity and frequency, so that an attack of grand mal occurred once in three or four months. The patient commenced to use alcohol in the form of beer. He observed that since then the convulsive seizures became more frequent. Moreover he relates that an attack would occur more frequently after a drink than when he would not drink. When he decided upon abandoning the acquired habit and observed strict abstention for the following eight months, he eventually noticed great improvement in his general condition and diminution of the number of convulsive attacks. This case also presents strong indications in favor of epileptogenetic character of alcohol. This contention finds its corroboration in the observations of men of great competence such as Magnan who as far back as 1869 described epilepsy from acute absinthism. In 1852 Delasiauve observed epilepsy as a complication of delirium tremens and he described it in the *Revue Médicale* under the name of "Une forme grave de delirium tremens." While the epilepsy is, so to speak, accidental in the cases without a previous history of epilepsy, nevertheless it appears to be caused directly by the alcoholic intoxication. The correctness of this view is seen particularly in the fact that when the toxic material is eliminated no attack takes place. The condition is analogous to the convulsive seizures in children in the acute stage of infectious diseases.

In considering the second category of cases, namely, those of chronic alcoholism, we must discriminate several varieties: in one we meet with cases in which epileptic convulsions occur after an excess of drink. Here the convulsion is probably due to a temporary congestion of the cerebrum. In another group we find cases in which, without incidental excesses, and many years after the habit had been acquired, epilepsy develops. It is evident that the latter makes its appearance only at a certain age, usually between 40 and 55. Contrary to what we observe in the acute alcoholism, which by itself is apt to cause convulsions, which occur at a young age, in which during abstention from alcohol no convulsions occur, here in chronic alcoholism the convulsive attacks continue to occur at intervals and generally speaking are not the result of any tangible cause. Evidently it is a case of a special convulsive predisposition which eventually becomes constitutional. The patient evidently is a carrier of organic alterations upon which the convulsions depend. This is the most serious form of alcoholic epilepsy. The convulsions are probably due here to the sequelæ of meningo-encephalitis, caused by chronic alcoholic intoxication. Shrinkage of the brain due to an increase of connective tissue and an atrophy of cerebral tissue; pachymeningitis degeneration of blood-vessels leading to miliary aneurysms, and cerebral softening from embolism or hemorrhages—those are the common findings in chronic alcoholism. The latter form of alcoholic epilepsy in which the convulsions occur intermittently and which are irremediable was first emphasized by Magnus Huss (*Annales Médico-Psychologiques*, 1853, p. 80) and later by Bratz (*Allegemeine Zeitschrift f. Psych.*, 1899, t. lvi., Juni 3). The authors claim that this is precisely the form of alcoholic epilepsy which is transmissible through heredity. That chemical changes produced in the germ cells by alcohol are capable either to create abnormalities in offspring or else loss of power of reproduction is now pretty well established. The latest work of Ch. R. Stockard and G. Papanicolau seem to place this problem on a firm basis. They show experimentally that the offspring of the third generation are more decidedly injured than those of the first. These experiments suggest that the chief bearer of the hereditary qualities which they call chromatin is pathologically affected in alcoholized parents. The descendants of alcoholized males include a large proportion of degenerates, deformities, abortions, early death of the young, and sterility begins to manifest itself in those which survive. The structural defects affect mainly the central nervous system and special sense organs. These important data indicate very strongly at least one of the reasons of epileptic convulsions in chronic alcoholism.

The opinions on the pathogenesis of alcoholic epilepsy are divided: some believe that autointoxication from the abdominal viscera, such as liver and kidneys, is the primary cause. Such is the opinion of Donath, Guidi, and especially of Ceni. But autointoxication may originate in the chemical processes of glands with internal secretions. Lévy and Rothschild in France, Parhon and Goldstein in Rumania have recently advanced this view. Disturbances in the internal secretions influence cellular metabolism and thus toxic material is elaborated. If the main problem is in autointoxication, the sources of the latter may be abdominal viscera, ductless glands, and cellular metabolism. In chronic alcoholism the entire economy is fundamentally disturbed. Toxic material therefore is constantly being elaborated. There is another view held by Jauregg according to which the chronic alcoholic individual possesses a certain poison which may be

called alcohologenic toxin by analogy with the bacterial toxins elaborated in the course of infectious diseases. In the course of and because of prolonged alcoholic intoxication, this special toxin is being accumulated and produces epileptic discharges.

In the foregoing pages two groups of cases of chronic alcoholism have been considered, one in which epileptic convulsions occur à propos of an incidental excess, the other in which they develop after many years' use of alcohol and without any apparent exciting cause. There is a third group of cases in which the seizures appear when, for therapeutic purposes, the patient is suddenly deprived of his habitual dose of alcohol. As an illustration, the following two cases are cited:

Case I.—Middle-aged business man, used alcohol for 25 years, at first in large quantities, but later more moderately. He began to suffer from gastrointestinal disturbances; there were also cylindroids and casts in his urine. For these reasons attempts were made to withdraw the alcohol abruptly. On the first day of the treatment the patient received no drink whatever. That night he was restless and could not sleep. He was slightly delirious. His pulse became rapid and he perspired very freely. Alcohol was then given him in half of the amount he was used to, namely, three tablespoonfuls of whiskey a day for the following week and then again an attempt was made to withdraw it abruptly. At the end of 12 hours he suddenly became unconscious and had a typical attack of epileptic convulsions. During the following month he was given again three daily rations of whiskey, but in a smaller quantity. Another attempt of sudden withdrawal was made and again the patient was seized with a convulsive seizure. From that time on the patient was given for three months a daily quantity of whiskey, but in a gradually diminishing proportion so that one teaspoonful was the dose reached at the end of that time. While the gradual reduction was going on he was kept on small doses of strychnine. No more convulsions occurred after the last withdrawal of alcohol. For six months the patient was under observation and he did not drink. Soon, however, while away from the city, he resumed his old habit. He was then brought again for treatment. Cautiously after a delay of a week his whiskey was suddenly withdrawn, that is, he did not receive the first two drinks of the forenoon. At 3 P. M. he was seized with a convulsive attack. Alcohol was resumed. Since then the patient has been lost sight of. The patient's previous history reveals the fact that at the age of 3 and 7 he had several attacks of convulsions. It is therefore possible that a convulsive aptitude or predisposition existed in this individual, and that the withdrawal of alcohol acted as a break in the continuity of the acquired alcoholic habit; hence it acted as an exciting factor.

Case II.—Woman of 50 had been using stimulants since the age of 30. Several times during that period she was placed in a sanatorium for treatment. While she was willing and even anxious to get rid of her alcoholism, she nevertheless was in a constant state of fear to bring on attacks of convulsions which occurred during the first attempt at forced abstinence. For this reason she did not remain long enough in a sanatorium and instead of a long and continuous period of treatment, she left the institution several times. The first trial consisted of a sudden withdrawal of all alcohol. This was followed within a few hours by a convulsive seizure with loss of consciousness. The second attempt was made after a period of three weeks, during which time a reduced amount of drink was given. Four attempts were made and each was followed by a convulsion. During each interval smaller and smaller quantities of stimulants were allowed to the patient. The latter finally refused to continue the treatment. The patient's previous personal history was negative, but her grandfather on her mother's side, and a brother of her father, were profoundly alcoholic.

An analysis of all the facts concerning the occurrence of epilepsy in alcoholism leads logically to the conclusion that there must be a direct relationship between epilepsy and chronic alcoholic intoxication. On the other hand, since epilepsy or epileptoid states do not occur in all cases of alcoholism, a question arises as to the underlying reason for such a disparity. If, as some believe, a morbid predisposition is an important factor in the pathogenesis, such a conception can be applied to some cases but not to all, as there are cases of alcoholic epilepsy in which no pathological predisposition can be traced. It is more logical to admit that alcoholic intoxication produces cerebral alterations more or less pronounced. In the acute variety, as in acute infections, cortical alterations are capable of producing convulsive seizures, but they are only transient. In the chronic variety of alcoholic intoxication we find permanent lesions of chronic meningitis or meningo-encephalitis with superficial sclerosis of a diffuse nature, which are the direct causes of epileptic attacks, and in view of the permanence of the lesions we observe attacks of convulsions even without incidental excesses. The rôle of developmental defects in the central nervous system produced in the germ cells of alcoholized parents has been sufficiently emphasized in the above mentioned experimental work of Stockard and Papanicolau. Statistical studies concerning the direct relation of alcohol to epilepsy reveal the following instructive data. Magnan (*Annales Médico-psychologiques*, vii, 1872, p. 52) finds 11 per cent. of alcoholics having attacks of epilepsy. Drouet calculates 10 per cent. (*Annales Médico-Psychologiques*, xiii, March, 1875). Echeverria finds 38 per cent. (*Journal of Mental Sciences*, 1881). Moeli gives 33 per cent. (*Neurologisches Centralblatt*, Nov., 1885). Furstner figures 38.8 per cent. (*Archiv für Psychiatrie*, xxviii, Feb., 1896). Stepanoff speaks of 46 per cent. (*Revue Neurologique*, 1900). The views concerning the presence of toxic elements and the material changes produced in the cerebral tissue in alcoholized individuals, also profound congenital deficiencies derived from morbid alterations in the germ cells of parents suffering from chronic alcoholic intoxication—are all sufficient data for the elucidation of the pathogenesis of alcoholic epilepsy.

THE MEDICOLEGAL ASPECTS OF RADIUM-THERAPY.*

By JOSEPH B. BISSELL, M.D.,

NEW YORK.

VISITING SURGEON, ST. VINCENTS HOSPITAL; SURGICAL DIRECTOR, RADIUM SANATORIUM OF NEW YORK; CONSULTING SURGEON, HOSPITAL FOR DEFORMITORIES AND JOINT DISEASES; DIRECTOR AND VISITING SURGEON, BELLEVUE HOSPITAL.

All remedial agents used in the art of healing are subject to various forms of application which may result through proper use in a relief of the condition treated or by improper application may bring about disastrous results to the patient and to the practitioner alike. Damages accruing from faulty instructions of a mechanical engineer may quickly cause a financial loss enormous in proportions. It is rare that we find mistakes evidenced in the chemical formulas evolved by the operators laying out work in our great commercial organizations. In that branch of science which has for its purpose the

study and treatment of the human body we unfortunately find all too frequent evidence to show that mistakes, errors in judgment, and lack of technical knowledge play sad havoc in their results. It is therefore most fitting that we bring to your attention the true status of affairs that may relate to the application of radium in medicine and surgery.

The Local or External Application of Radium.—Possibly, no subject in medicine or surgery has so widely interested the lay public as has radium. This interest is stimulated by belief that there may lie in this substance that which will ultimately bring us a cure to the most horrible of all diseases, cancer. That we can reasonably look forward with an ever-increasing degree of hope in this agent is made clear by the remarkable success that is being attained in the treatment of malignant conditions purely superficial in type. The clinical improvements and apparent cures in those cancerous masses to which radium can be directly applied run well over 80 per cent. and are increasing in proportion with our knowledge of better technique and an understanding of accurate dosage. It will further interest you to know that those deep-seated growths located in the interior of the body, in its cavities, etc., held as incurable, are giving increasing promise as we find means of applying this active element directly to the mass. It would not be proper in making such statements as this to lay the entire claim for this beneficient influence on radium alone. We must clearly understand that radium is but one of the means at the command of the surgeon and we must rely upon his ability to know when to discontinue his work with the knife and take up another instrument whose application is far more humane and yet deeper and more effective in its power. The space allotted to me will not permit me to go into the various forms of technique used in the treatment of the types of cancer that come to the surgeon for remedy.

Internal Use of Radium.—More than ten years of clinical achievement at the great hospital centers of Europe where radium has been used internally give us certain definite knowledge as to its value for the treatment of many diseases dependent on early degeneration of the kidneys, heart, and blood-vessels associated with imperfect elimination of the body's waste products causing self-poisoning of the patient. Such diseases as nephritis, arteriosclerosis, and various forms of arthritis or rheumatism, so called, which we commonly know to incapacitate so many men in early years are now held as curable or controllable to a large degree by radium-therapy, properly administered. Innumerable are the channels of hopeful therapy that follow the administration of the emanation of radium in cases evidencing faulty cell activity and circulatory changes.

Let this suffice as a general classification for the more common indications for the use of radium in its various forms and from such a theme, let us make our deductions as to the medicolegal aspects resultant from the use of radium. When radium is applied locally we look forward to certain anatomical and physical changes. If the type of the mass and the character of its cell structure are thoroughly understood we will hope to see its activity of growth checked, the tumor being decreased in size, either without any apparent breaking down of its structure or by degeneration of the mass and a general sloughing off of its substance. Under successive treatments the classic result shows a disappearance of the growth entirely. Where such results are not to be obtained due to the uncontrollable activity of the cancer cell we may be justified in answering that as yet there is little to hope for in the way of promised cure, but we may apply radium in such a case, because of our definite knowledge that radium will largely control the hemorrhage, reduce the odor, hold in check the symptom of pain, modify to a large extent the active congestion present, and restore to the patient hope. These briefly are the possibilities for local application.

The medicolegal aspects of such treatment will depend on two general classifications, the ability of the surgeon in diagnosis and statements relating thereto and the quality and quantity of the radium element at his command and his ability to estimate proper dosage. It is most natural to assume that the practitioner would hesitate to specialize in the treatment of malignant diseases either with the knife, caustic pastes, or radium unless he had derived extensive knowledge as a clinician and was backed up with suitable laboratory facilities to insure correct diagnosis. It is the duty of the operator for his own protection and for the benefit of the patient to know as far as possible the exact type of the growth to be attacked. Certain types of cancer present tremendous activity in growth and require a large amount of radium coupled with long periods of application. Other structures exhibiting cell growth of lower vitality can easily be treated with smaller dosage. Then again there are certain locations in the human body, such as in the region of the mouth and throat, wherein we are possibly not justified in making any operative procedures even for microscopic examination. In this region active growth most grave in its type frequently follows surgical interference.

So far as radium itself is concerned there are four possible channels of danger from its applications; namely, from a dosage applied in regions like the bladder, stomach and esophagus resulting in a burn following which might come penetration, infection, and death; secondly, from the possibility of activating the growth of cancer cells by an insufficient dosage; thirdly, the possibility of danger from the action of radium directly on the walls of large blood-vessels lying in the immediate vicinity of the mass treated, causing a rupture of the blood-vessel and fatal hemorrhage following the effects of a burn; fourthly, the possibility affecting the ovary when radium is applied in regions in close proximity to it. Radium burns in general have no terrors. A troublesome burn at times will occur where an extremely large dose of radium has been given and screened with most careful technique. There are certain cases, such as those of extreme malignant type met in the throat, that we treat with the heaviest dosage possible with the full expectation that we will get a deep severe burn. We would not be giving sufficient dosage did we not get such a manifestation. The one hope in a desperate case of cancer of the tongue is to give the man the heaviest dose of radium possible and screen it in such a manner as to permit him to secure practically all the available energy of the radium. He

is therefore told that a burn will probably develop and every such radium patient should be similarly warned. There is absolutely no danger in a radium burn other than penetration. The surface heals slowly, sometimes taking weeks and months to recover. At times following heavy ray treatment we find a resultant heavy layer of fibrous tissue which may remain permanently.

Undoubtedly, insufficient dosage of radium at times tends to increase the growth and activity of cancer structures. This cannot be held, however, in condemnation of radium because in all probability at the stage reached any interference, whether it be a knife, caustics, or radium, would possibly exert the same influence. However, it is extremely important that a proper dosage be administered. The serious consequences coming from the application of radium without every precaution in the neighborhood of large blood-vessels would undoubtedly be a reasonable subject for medicolegal consideration. Properly administered, radium has been used in this country in local application with doses varying from two milligrams to one thousand milligrams without effecting burns which would have any medicolegal aspects. Of course, such treatments were carried on with perfect technique. In working in the vicinity of such organs as the eye, one must naturally protect, by sufficient screenage, that portion not affected by the cancer. Nature has considerately protected the radium worker by giving resistance to normal tissue of many times that of the cancerous structure and therefore it is possible for us to apply very large dosage, destructive in type, to the cancer mass and not do serious damage to adjoining tissue. Radium should in no wise be considered a cautic or tissue-destroying agent. Its destructive properties come from the action of radium directly on the blood-vessels of the structure. There may possibly be a further action on the intercellular substances; the nutrition being cut off from the mass causes its death and degeneration. There are but few opportunities for a scientific worker with radium to make mistakes and we trust that so powerful and energetic an agent as radium will not be placed in hands improperly schooled. The dangers of the gamma ray from *x*-ray treatment are of common knowledge to everyone, and we find some people confuse the gamma ray of that apparatus with radium. They are analogous but not at all similar, and where the *x*-ray burn at times develops into cancer the radium burn is inert and is itself used to cure the *x*-ray malignancy.

With, then, practically nothing to fear from the proper use of radium and but few opportunities for mistakes, the medicolegal aspects rapidly dwindle to practically nothing. The sins of radium are more of omission than of commission.

Just a word relating to the internal administration of radium. This branch of radiumtherapy is of equal importance with the local application and its responsibilities are often greater. With radium it is possible at times to restore to usefulness the man who in the prime of life is crippled to invalidism by a rheumatic affection.

Radium may serve to control certain of the dangers of high blood pressure commonly met in the arteriosclerosis case or markedly influence the metabolism and elimination in cardiac and nephritic patients. If such results are forthcoming from the use of radium emanation then it is truly a most important remedy. With this in view, let us ask ourselves the question, What is the danger or medicolegal aspect as relates to the internal administration of radium? In answer to this I would say that experience has shown that radium is accepted as harmoniously in the body as is sunlight by the withering plant. Doses have been administered to use a common unit of from 500 M. U. to 27,000,000 M. U. of emanation without danger or harmful influence. Radium injected into the blood can easily be traced in its elimination, and while it is active for many weeks, its complete disappearance from the body is assured. Definite measurements governing elimination are at hand. There seems to be no evidence that would point to any danger from radium when used internally. One point of warning, however, must be offered. Unqualified practitioners, poor diagnosticians, and men lacking clinical experience could, of course, make mistakes and cause damage even with radium. It is to be regretted that there are still men in the practice of medicine who are not qualified by an experience or ability to be treating human kind. If we have an extremely high blood pressure of the compensating type, such pressure possibly should not be reduced. It is accomplishing its purpose. The only reduction that should be attempted in such a case would be that secured by a combined treatment of both cause and effect. That radium does exert a remarkable influence in the treatment of arthritis, gout, and diseases of faulty elimination in general must be acknowledged, and the time will soon be at hand when the practitioner who does not use all measures of treatment at hand before failing in his arteriosclerosis cases, in administering aid to his desperate rheumatic patients, and who does not relieve those diseases of the heart and kidneys by advanced measures of therapy when indicated, will be guilty of malpractice, and so charged.

46 West Fifty-fifth Street.

GAS BACILLUS INFECTION IN A CHRONIC MASTOIDITIS WITH CHOLESTEATOMA; OPERATION, RECOVERY.*

By WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.,

NEW YORK.

The following is a report of a case occurring in my service at the Gouverneur Hospital:

The patient, a large, powerfully developed Russian, 32 years of age, was admitted March 16, 1917. The family history is unimportant. Aside from the ear condition leading up to his present illness, patient has always been strong and healthy and says that he was never really sick before in his life. He denies venereal history and says that he neither drinks nor smokes.

Following an attack of grip two years ago he had an abscess in his right ear. At intervals since this time he has had pain and a discharge of pus from this ear. He has never received treatment for this condition. At times the pain in his ear has been very great, but it has always subsided after a profuse discharge of pus.

For three months he has had a bad cold in the head, and for the past month he has had almost constant pain in the right ear. Several days ago the discharge from his ear increased greatly. On the day before his admis-

*Read before Otological Section of the N. Y. Academy of Medicine, May 11, 1917.

sion to the hospital he had a chill, followed by fever and sweating. The tissues around the ear became swollen and painful, and this condition gradually extended over the whole side of his face and head.

Examination shows the following condition.: General appearance of patient is that of a very sick man. Tem., 102°; pulse, 90; resp., 24. Right side of the face is paralyzed, right eye almost closed, entire right side of face, neck, and head greatly swollen and skin is dark red in color. The limit of the swelling is fairly distinct, but it has not the prominent line of demarcation characteristic of erysipelas; then, too, the swelling is bulging in character, the most prominent point being over the mastoid antrum. There is a foul, purulent discharge from the right ear. No attempt was made to inspect the drum, as the canal was closed by the swelling. On account of the pain and swelling the patient can scarcely open his mouth wide enough to take nourishment. The entire swollen area is very painful to the touch. Firm pressure with the fingers gives a sense of fine crepitation, which is combined with that of fluctuation over the mastoid. Blood examination: White cells, 12,000; polymorphonuclears, 78 per cent.

Operation: The usual incision for mastoiditis was made. As soon as the knife penetrated the deep layers of the skin a most unusual phenomenon was observed; the blood oozing from the wound appeared to be charged with gas which was escaping in fine bubbles. The incision was made fully an inch and a half deep through the edematous, emphysematous tissues before the periosteum was reached; as soon as this was incised there was an almost explosive discharge of foul-smelling gas, followed by thin fetid, greenish-yellow pus. The odor of this discharge was said by all of those present to be identical with that of other cases of gas bacillus infections treated in the hospital. Subperiosteal elevation of the tissues extended over the entire right side of the head.

There was a large perforation in the mastoid cortex, at a point corresponding to the antrum. The entire mastoid process, with the exception of the extreme tip, was occupied by a cholesteatoma, which extended also into the middle ear. The posterior bony wall of the auditory canal was completely destroyed. The small vessels lying upon and entering the bone over the entire affected area presented a very unusual appearance; they were thrombosed and resembled fine black hairs.

The cholesteatoma and the tip cells, which were filled with pus, were thoroughly removed and all overhanging bone was curetted away. Free counteropenings for drainage were made through the scalp; one near the parietal eminence and one near the occipital protuberance. The wound was irrigated with hot normal saline solution and packed with iodoform gauze.

A culture made from the wound pus showed a mixed infection, including large numbers of giant rod-shaped gas bacilli. These bacilli are Gram-positive, are about 5μ in length and about the thickness of anthrax bacilli. They correspond to the description of the Welch bacilli, which have been described also by Nutthall, Flexner and others. Following the operation the patient showed almost immediate improvement. The temperature in two days dropped to normal; his recovery was uneventful, and he was discharged from the hospital on April 5, nineteen days after admission. The wound has since healed entirely. The gas bacillus is anaerobic; it cannot live in oxygenated circulating blood. It would seem, therefore, that an old cholesteatomatous mastoid would offer ideal conditions for its propagation when once it has gained an entrance.

Interesting features of this case are:

1. The rarity of gas-bacillus infections of the mastoid.

2. The unusual route through which the infection gained an entrance; namely through the middle ear; the usual mode of entrance of this bacillus into the body being through an open wound or abrasion into which earth has been ground.

3. The prompt recovery following the operation, an unusual sequel to gas bacillus infections, for these cases usually succumb very quickly.

69 West Fiftieth Street.

Medicolegal Notes.

Result of Patient's Refusal to Follow Advice.—The Minnesota Supreme Court holds in an action for malpractice against a surgeon that where a patient refuses to submit to the reasonable treatment prescribed by a surgeon, from that time on the fault is with the patient and not with the surgeon, and the surgeon may give in evidence his opinion of what the result would have been had the treatment which he prescribed been followed. The plaintiff had sustained a fracture of both bones of the right forearm between three and four inches from the wrist, and was treated by the defendant. The ends of the ulna failed to unite. The evidence conflicted as to the character of the services actually rendered, and the surgeon claimed that a complete cure did not follow the treatment because of lack of bone-producing power in the arm. He stated that he had advised the plaintiff that further methods were necessary and that he would have to give him another anesthetic and treat the ununited ends of the ulna so that they would unite, and that the plaintiff refused to submit to such treatment. Upon the trial six physicians were called and testified as expert witnesses for the defendant, and each testified that the treatment of the plaintiff as outlined by the defendant was proper and in accordance with modern surgery. The court said: "If defendant's claim of freedom from fault is well founded, a question he had a right to have submitted to the jury, it was his duty, upon discovery of the nonunion, to advise plaintiff of the necessary and proper treatment to be thereafter pursued. Proper advice is part of proper treatment, and if from that time on there was fault in any one, it lay with plaintiff, and not with defendant. It was defensive matter going directly to disprove the charge in the complaint, and not in mitigation of damages or to establish contributory negligence. Defendant claims that in this respect as well as in all others he performed his whole duty toward plaintiff, and in connection with his advice he had a right to state to the jury his opinion as to the result of the treatment he prescribed had it been followed. The testimony sought to be elicited was admissible under the pleadings, and it was error to exclude it." Judgment for the plaintiff was reversed and a new trial was ordered.—Peterson vs. Branton, 162 N. W. 895.

Privileged Communications.—The Nebraska Supreme Court holds that under the statute relating to privileged communications, when a plaintiff has permitted a physician to make a radiograph of his injured foot for the purpose of ascertaining the extent and character of his injuries, the radiograph so made is not admissible in evidence over objection of the plaintiff based upon the statute.—Stapleton vs. Chicago, B. & Q. R. Co. 162 N. W. 644.

Practice of Medicine by Corporation. — In an action against a medical society for malicious prosecution of the plaintiff for practising medicine without a license the New York Appellate Division holds that a business corporation cannot administer in its own name medicine in treating disease or physical condition, which under New York Public Health Law, Section 160, is practising medicine, even if it does so on the advice or prescription of a licensed physician in each individual case. The administering of treatment which included the giving of pills and of some liquid substance for the purpose of curing the liquor and drug habits, was held to be the "practice of medicine." A corporation which treated persons afflicted with the liquor habit and employed a physician whose compensation was paid at stated intervals, without regard to the number of cases, and who prescribed the treatment which the corporation was administering without having any knowledge of what the treatment consisted of, was held to be guilty of practising medicine without a license, since the employment of the physician was manifestly only a sham to evade the law, so that there was probable cause for prosecuting the corporation for practising medicine without a license. Evidence that the physician employed to prescribe the treatment administered by the plaintiff had made no inquiry or examination to ascertain the ingredients of the medicines prescribed was held competent to show that the physician's prescription was a mere pretence. Judgment for the plaintiff was reversed and the complaint dismissed.—Godfrey vs. Medical Society of New York County, 164 N. Y., Supp. 846.

Military Medicine.

Blood Pressure During Operations on the Wounded Abdomen.—Geoffrey Marshall states that during the course of an ether vapor anesthetic the blood pressure shows a tendency to rise, but if there is much manipulation of gut and mesentery, it will gradually fall. The process may continue for hours without the pressure falling to a dangerous level. Exposure of gut outside the abdominal cavity produces a much more serious effect; if more than two or three feet are exposed, the blood pressure will commence to fall after a few minutes, and will continue to do so rapidly until the gut is replaced. This is seen when stomach and omentum are exposed and even with great omentum alone. The indication is that surgeons should make big incisions and work with the gut lying inside the abdomen as far as possible. Covering the exposed gut with hot saline does not prevent the fall of blood pressure. Exposure of the gut produces far less effect if the patient is not under an anesthetic. Men arrive with several feet of intestine prolapsed through a wound, yet their blood pressure is within normal limits. In one case more than two-thirds of the small intestine had been outside the abdominal cavity for at least four hours, yet this man's blood pressure was 142 mm. of mercury and his pulse rate only 108. The patient recovered.

Apart from copious hemorrhage, there is one other procedure which causes rapid fall of blood pressure in cases of abdominal operations. This is turning the patient on his side. The effect is only seen if the patient has been under the anesthetic for a considerable time before being turned. At the end of an abdominal operation the patient may be in good condition; he is then turned on his side so that the surgeon may excise a wound in the back. In a few minutes there is a fall of blood pressure and the radial pulse disappears. It may be hours before the patient recovers this lost ground. If possible wounds of the back should be dealt with before laparotomy, as turning the patient has no ill effect during the first half hour of an ether anesthesia.

If chloroform be used in these abdominal operations, the blood pressure will fall during administration and for some hours afterwards. The intrathecal administration of stovaine is unsafe, and should not be employed.—*British Medical Journal*, June 2, 1917.

Results of Clinical and Experimental Study of Three Hundred Perforating Wounds of the Abdomen.—There has already been given the experimental work carried out by J. Fraser and Hamilton Drummond with reference to this series of cases (MEDICAL RECORD, April 14). In their work on these cases at the hospital the following features were observed and carried out with reference to operative procedures upon the various injured abdominal organs: In wounds of the stomach, while entrance and exit wounds of the body are very similar in size, an exit wound in the thicker musculature of the pylorus is generally larger than the entrance wound and if bile has escaped from the stomach wound the peritonitis is much more severe. Sickness is usually more pronounced than in wounds of the other abdominal viscera, and blood is usually present in the vomitus; while the degree of collapse is less marked than that found in intestinal injuries, whether the small amount of hemorrhage influences this is not known. While the pulse and respiration rates are both increased, the respiration rate has increased proportionately more rapidly than the pulse rate. Naturally the situation of the wound influences the degree and variety of the symptoms. Pain is more intense when the cardiac and pyloric ends of the stomach are involved, than when the body is the seat of injury; while wounds of the curvature are associated with severe symptoms of collapse, due to the greater amount of destruction of tissue. Again the clinical features are more intense if the injury occurs when there is food in the stomach.

In the treatment, a routine examination of the posterior wall of the stomach should be made, as a wound in this region is apt to be overlooked. Wounds of the cardiac region which are inaccessible for suture may be safely left unless the tear is a large one, since natural healing will occur with little or no leakage.

In wounds of the pelvis, the writers remark how seldom there is a massive escape of contents from the lumen of the gut. Apparently there is a complete inhibition of peristalsis for some time subsequent to the injury. Often when a bullet passes through the pelvis the loop of intestine lying in the path of the bullet will be found riddled with holes over a very limited area. A serious type of injury is when the intestinal contents have escaped between the layers of the mesentery. They have been in cases where the projectile has not actively perforated the gut, but, by passing near it, has exerted such a force that the gut wall ruptures in that portion which is unsupported by peritoneum —between the layers of the mesentery.

In the operative treatment, there would seem to be very few wounds of the small intestine which do not prove amenable to suture. There are three possible contraindications to its use: Extensive damage to the mesentery; a wound, which when sutured results in marked narrowing of the gut, which is usually a wound running obliquely across the long axis of the gut; and, when the perforation is associated with resulting necrosis of the surrounding bowel, a condition more common in the colon than in the small intestine. In their suture operations they have not excised the edges of the wound and have used a linen thread for stitching. Where resection is to be done, lateral anastomosis is the favorite method of procedure, and no complications occurred with recovery as the invariable result.

In wounds of the duodenum there is a high mortality before surgical assistance can be rendered, due to the proximity of large and important organs. The injuries usually occur to the second part of the duodenum with an associated wound of the right kidney. Hemorrhage is not generally severe. There is intense shock and sickness is usually present. Operative treatment consists in suture of the torn bowel, with the possibility at the same time of performing a gastroenterostomy.

In wounds of the colon there is effusion which has a tendency to become shut off and localized, more especially in wounds of the ascending or de-

scending colon. Effusion often extends into the retrocolic and retroperitoneal tissues, and is fatal when it occurs. Colon wounds appear to be liable to secondary hemorrhage, due to septic change in the gut, and it generally appears on the third or fourth day after operation.

Because of the localization of the effusion it is a wise procedure to enlarge the original wound in the operation on the possibility that the infection is becoming localized, if the patient is seen longer than twenty-four hours after the injury has occurred. At an earlier period than this it is probably better to open the abdomen through a separate incision. There is danger of overlooking wounds in the colon and the risk is greatest when the wound lies in one or other of the flexures of the gut. The actual operative treatment may be summarized in the following methods: (1) Simple suture; (2) suture with a proximal colotomy; (3) colotomy at the site of injury. The operation of resection may be left out of account; it is rarely advisable to practise it in this type of surgery.

All wounds of the colon should receive very thorough local drainage. In wounds of the ascending and the descending colon they have been impressed with the advisability of draining the retrocolic space by a tube passing into the loin. The establishment of efficient local drainage is the means of lessening the likelihood of development of infection of the retrocolic tissue and the establishment of colon septicæmia.

Wounds of the rectum occur usually through entrance in the buttocks. The most common type is the wound of the anterior wall of the rectum, low down and immediately above the floor of the pouch of Douglas. The wounds are nearly always complicated by compound fracture of the pelvis or wounds of the small intestine or bladder. There may be much bleeding, but it is unusual to find intestinal contents escaping in any degree, unless the wound is very large. In the early stages the symptoms are ill-defined and easily overlooked. There may be recent hemorrhage from the rectum, retention of urine, or pain near the bladder on micturition.

Treatment demands an exploration of the abdomen. If an intraperitoneal wound exists, it should be sutured with a primary layer of catgut and a series of linen thread Lembert sutures. Temporary colotomy is to be considered. If the wound is extraperitoneal, the entrance wound is opened up and efficient drainage established. In every wound of the rectum it is advisable to open up the entrance wound very thoroughly as it diminishes the risk of a subsequent pelvic cellulitis. Colotomy in this type of wound depends on the character and position of the wound.—*British Medical Journal*, March 10, 1917.

Antiseptic Solutions for the Dressing of War Wounds.—The editor of the *Revista de Medicina y Cirugía* (May 10) discusses in succession Dakin's solution, the Carrel technique, Duret's solution, the Vincent treatment, the new Browning antiseptic, the iodized chloroform of Chassevant, and the ambrine of de Sandfort. The first two and the last of these are well enough known to the average reader. With the others, however, we are not so familiar. Duret's isotonic solution contains from first to last magnesium hypochlorite, chloride, carbonate, hydrate, and oxychloride. The basis of the solution is prepared by triturating in a mortar 28 parts of calcium chloride and 18.2 parts of magnesium sulphate and adding little by little 1000 parts of water. The mixture is at once filtered through cotton, the filtrate containing nascent magnesium hypochlorite while the insoluble sulphur salt is left behind. When completed, the solution is both antiseptic and isotonic with blood serum. When applied to wound surfaces chlorine is given off from the hypochlorite, eventually combining to form chloride, hydrate, and oxychloride of magnesium. The solution warmed to 35° C. is used for irrigating the wounds just after the application of hydrogen peroxide solution, one part to nine. The innumerable bubbles liberated by the latter penetrate into the deepest recesses of the wound surface, giving a mechanico-chemical detergent effect. The surface is thereby prepared for the hypochlorite solution, which also washes all the foam from the wound surface. Professor Vincent of Val de Grace Hospital uses a solution of calcium hypochlorite and bone acid originally tested by him many years ago for hospital gangrene in Madagascar. The new antiseptic of the Middlesex Hospital, London, prepared by Browning of the Bland Sutton Institute of Pathology from aniline colors is a powerful germicide which stimulates wound healing and does not injure the phagocytes or irritate the tissues. Chassevant's solution of iodine in chloroform was recommended by him as an antiseptic as far back as 1905. Since then iodine has come to be known as one of the most practicable antiseptics. Dissolved in chloroform it is quite free from irritant properties if the proportion does not exceed 1 to 30 by weight. Manifestly the alcoholic tincture and the iodoiodide aqueous solution are unsuitable for the purpose and it is evident that the germicidal power of iodine does not run parallel with its irritating properties. The reviewer fails to mention Mencière's solution, the basis of which is ether, for the routine treatment of wounds. It is significant that Dakin, Duret, and Vincent have all selected a hypochlorite as the most available antiseptic.

Gas Masks on Warships.—Every American naval vessel which sails for the war zone carries a full equipment of gas masks. Gas shells have been used by the German naval gunners, and it was deemed necessary to equip American boats against such devices. A type of mask adopted for the emergency was turned out quickly after approval by a special committee of the National Defense Council.

Red Cross Director.—Harvey D. Gibson, president of the Liberty National Bank, New York, has been appointed general manager of the Red Cross. Part of Mr. Gibson's duty will be to develop chapters and add to the membership of the society. John D. Ryan, president of the Anaconda Copper Company, has been assigned as director-general of military relief of the Red Cross. He will be in charge of all the relief work for the fighting forces, succeeding Col. Jefferson R. Kean, who has been ordered to take command of the 160 United States Army ambulance sections in the war theater.

Women Physicains of the Coast Ready for War Work.—Many of the women physicians of Los Angeles, Cal., have signed a petition signifying their willingness to undertake medical service at the front. The petition is as follows: "We, the undersigned, offer our services to the War Department as members of the Medical Reserve Corps, and will serve wherever sent, providing that opportunity of medical service be given to medical women equal to opportunity given to medical men, both as staff members of base hospitals and otherwise, and that women who serve be given the same rank, title and pay given to men holding equivalent positions."

Medical Unit Proposed by the American Electrotherapeutic Association.—This association has arranged a plan to carry out their bit in connection with the injured soldiers in the war. Dr. William Benham Snow announces that the purpose of the unit is to furnish facilities and men to carry out in a thoroughly scientific manner treatment by electrotherapeutic and other physical methods of diseased conditions arising from injuries and from other causes associated with exposure of our men in the army at the front. The scope of the work will include the treatment of infected wounds, delayed repair following injury, beginning gangrene, sprains, contusions, atrophies, various forms of arthritis, erysipelas, frost bites, trench foot, flat foot, and neuritis. In order to do this work properly sufficient funds will be provided thoroughly to equip and maintain a unit. The committee recommends that such a unit form a part of every base hospital in this country and abroad. There are qualified physicians in readiness to fill these positions. The equipment should include transformers and diathermic apparatus, *x*-ray machines, therapeutic lamps, sinusoidal machines, and constant-current apparatus.

Training for Medical Corps.—The doctors in the Medical Training Camp at Fort Benjamin Harrison are put through a rigorous program each day, the strenuousness of which is lessened somewhat on Sundays. The daily routine is as follows: 5:30, reveille, followed by a "setting-up" drill; 6, breakfast; 7, military drill; 8:30 to 9:30, lecture or conference on military medical work; 9:30, drill; 11 to 12, conference; 12, dinner; 1:30 to 2:30, conference or lecture; 2:30 to 3:30, road march. The remainder of the afternoon and evening is devoted to study for the next day's work, and at 9:30 "taps" is sounded by the bugler. The lectures are given by instructors, and ofttimes by doctors who are members of the companies. Each company has a medical officer of the Regular Army as its captain, but the other offices in each company are filled from the ranks of the men themselves. All of the doctors wear officers' service uniforms. They have no dress uniforms. While within the limits of the reservations they do not wear any shoulder bars to denote their rank, because of the idea prevailing in the army that all men are on equal footing while in training. The doctors are just plain "rookies," but when they leave the reservation and go to town they are permitted to wear the insignia of their rank, and are saluted in military fashion. All of the men must be smooth-shaven. They are quartered in small frame barracks, each building accommodating from forty to fifty men. Each man on his arrival has to be his own orderly and arrange his own belongings.

Hospital Donated for War Cripples.—To meet the need of the men who will return from the front crippled, the Government has arranged for three reconstruction buildings to be either built or made out of private homes given by men of wealth. The first to be ready will probably be the home of Mr. and Mrs. Charles D. Freeman at Iselin, N. J., a 600-acre estate on high ground, wooded and with country fields, an ideal place in which men may be brought back to health. It is estimated that the house will accommodate 250 patients when it is opened under the auspices of the Red Cross the last of August, and bungalow wards will be built in sufficient number to take care of 2000 patients. The hospital will be under the care of Dr. Fred H. Albee of New York.

Demonstration War Hospital Now Ready.—Following inspection, the first war demonstration hospital in the United States, now on the grounds of the Rockefeller Institute at Sixty-fourth Street and Avenue A, New York, is about ready for service, and will be shortly opened. Here army surgeons and Red Cross nurses will be taught advanced methods of surgery and caring for wounded, in preparation for work in American base hospitals behind the lines in France.

Sixteen Tented Cities for Guardsmen.—The War Department has authorized the construction of sixteen wooden cities for the new National Army. The sites already determined are: Fort Worth, Tex.; Fort Sill, Okla.; Deming, N. Mex.; Waco, Tex.; Houston, Tex.; Linda Vista, Cal.; Greenville, S. C.; Augusta, Ga.; Macon, Ga.; Montgomery, Ala.; Anniston, Ala.; Fayetteville, N. C.; Palo Alto, Cal., and Spartanburg, S. C. These camps will be laid out to accommodate approximately 35,000 men in each, and possibly as many as 10,000 horses and mules. Building waterworks and sewers for a population of 35,000 in about a month is a rapid undertaking and such work is merely a single detail of many similar pieces of work that must be done in each of these sixteen camps. The sanitation of these camps has received careful study. Special care is being paid to securing an ample supply of good water, to providing sewerage and sewage-disposal systems, and to the disposal of garbage. A number of sanitary specialists have been cooperating in the general plans for such work.

Red Cross Preparation for American Troops.—The American Red Cross, in Paris, has moved into new quarters in the Place de la Concorde, and has begun the establishment of canteens, restaurants, and dispensaries at railroad stations and junctions where the American troops will pass en route to the front. The canteens will supply food, and the dispensaries will have nurses and doctors in attendance. The same courtesy will be offered to the French troops, but such canteens are already in existence for the French soldiers. Many American women, all volunteers, are conducting this work.

Treatment of Trench Foot by the Subcutaneous Injection of Oxygen.—Captain H. Oswald Smith's article on this subject, an abstract of which was published in this department on June 23, appeared originally in the *British Medical Journal* of April 21. The credit was accidentally omitted.

APPLICATION FOR APPOINTMENT IN THE MEDICAL RESERVE CORPS, UNITED STATES ARMY

.....

....., 191

To the Surgeon General, U. S. Army,
Washington, D. C.

Sir:

I hereby make application to be examined for appointment in the Medical Reserve Corps, U. S. Army, and inclose testimonials as to my character and habits.

I certify that to the best of my knowledge and belief I am laboring under no mental or physical infirmity or disability which can interfere with the efficient discharge of any duty which may be required of me if appointed in the Medical Reserve Corps, U. S. Army, and that the answers given to the interrogatories below are true and correct in every respect.

I furthermore state my willingness to proceed to such point for examination as may be designated by the Surgeon General, with the understanding that the journey entailed thereby must be made at my own expense.

INTERROGATORIES

Where were you born? (Give State and city or county; if foreign born, give country.).....

.....

What is your name *in full* (including your full middle name):.....

What was the date of your birth?.....

When and where were you naturalized? (For applicants of alien birth only).....

Are you married or single?.....Have you any minor children; if so, how many?.....

What is your height in inches?.....Your weight, in pounds?.....

Give the nature and dates of all serious sicknesses and injuries which you have suffered:.....

.....

If either parent, or brother, or sister has died, state cause and age in each case:.....

Do you use intoxicating liquors or narcotics; if so, to what extent? .....

Have you found your health or habits to interfere with your success in civil life?.....

What academy, high school, college, or university have you attended? State periods of attendance from year to year, and whether you were graduated, giving date or dates of graduation:.....

.....

Name any other educational advantage you have had, such as private tuition, foreign travel, etc.:.....

.....

Give all literary or scientific degrees you have taken, if any, names of institutions granting them, and dates: .....

With what ancient or modern languages or branches of science are you acquainted?.....

How many courses of lectures have you attended? Names of colleges and dates:.....

.....

When and where were you graduated in medicine?.....

(Fill this out and send it to the Surgeon General, U. S. Army, Washington, D. C.)

Have you been before a State Examining Board? If so, state when, where, and with what result:*.....

.....

Are you a member of any State medical society? If so, give its name.....

Have you had service in a hospital? If so, state where and in what capacity, giving inclusive dates of each kind of service:.....

What clinical experience have you had in dispensary or private practice?.....

.....

Have you paid particular attention to any specialty in medicine; if so, what branch?.....

What opportunities for instruction or practice in operative surgery have you had?.....

.....

Have you previously been an applicant for entry into the United States service? If so, state when, where, and with what result (if rejected, state why).....

Are you a member of the organized militia? If so, state with what organization and in what capacity:

.....

Have you been in the military or naval service of the United States as cadet or otherwise? If so, give inclusive dates of service with each organization, designating it.....

What occupation, if any, have you followed other than that of student or practitioner? .....

What is your present post-office address?.....

What is your permanent residence?.....

Signature.....

The correctness of all the statements made above was subscribed and sworn to by the applicant before me this.....day of.....A.D. 191

[SEAL] .....

*This application must be accompanied by a certificate from the proper official that the applicant is duly registered to practise medicine in the State in which he resides.

New York, July 21, 1917.

FIRST IN THE FIELD.

As soon as our country had ceased to hesitate, had drawn the sword, and was sweeping to the aid of our allies across the sea, a generous rivalry sprang up among Americans of all classes and callings to see who could serve the cause the most. One point which was dwelt upon largely by the lay press was the race to see which organization or branch of the service would be the first in battle. Leaving out of the question the American Ambulance Corps and Hospital in France, and the Red Cross surgeons, whose services are as old as the war itself, the Medical Corps outstripped them all. As the *Military Surgeon* says editorially in its June issue, "While others have been talking and preparing the Medical Corps of the Army has been *doing*, as a result of previous preparation. It had numerous representatives abroad as official observers and on leave before the declaration of war by this country. Its representatives have for some time been at the front in large numbers, and they will be there in much larger numbers before any other branch of the service sets official foot on the continent of Europe." From civilian life, too, many physicians have volunteered their services in succoring the wounded in the battles yet to come. They have recked little that perils awaited them at sea on their way over, or that death in all its horrid forms was stalking over Flanders. They have seen only the bloody wounds, the maimed and twisted forms, crying aloud from the stricken field for help, and they have gone the road to France.

But there is another side to which we must not let our complacency blind us. Although first in the field, the American doctors are not there, and until recently were not offering to go there, in anywhere nearly sufficient numbers. Indeed, so reluctant did they seem to volunteer their services to their country that a dreadful fear began to shape itself that the medical men of the United States, who have so often shown their courage in war and in times of pestilence, had forgotten their high ideals, and with prosperity had grown soft or even cowardly. When the American Medical Association met in this city some of its officers proudly offered the services of 140,000 doctors to the country; but the 140,000 failed to respond when they were called, and the army then appealed for help to the medical press. At the annual dinner of the American Medical Editors' Association in this city, Major Noble of the Medical Corps of the Army and Dr. Bloodgood of Baltimore exposed the urgent need of the Government for some 20,000 surgeons, of which number the Medical Corps was short more than 17,000, with but a paltry few offering themselves each week, and they begged the editors present to make these needs known and to do what they could to bring their readers to a realization of their duty. The publicity given to these requests by the members of the Editors' Association has, we rejoice to say, had good results, and we are informed that the applications for appointment to the Medical Corps now number nearly a thousand a week.

This is good, and shows what the well-directed efforts of the medical press can accomplish, but it is not enough. More surgeons are wanted, and they are wanted immediately, for it takes time to train a civilian physician to perform properly the duties of a military surgeon, and the doctors will be needed when the new men obtained by the draft are collected in their training camps. They will be needed to care for these men while they are in camp and to accompany them across the sea when they go to help our allies cut out the foul Prussian cancer from the breast of suffering Europe.

We would, therefore, again urge the medical men of the Union, especially recent graduates and those without dependent families, to heed their country's call and to give themselves freely and without delay. On pages 109 and 110 will be found an application blank which can be filled out and sent to the Surgeon General's office in Washington. This is all that the applicant has at first to do, and, having done it, he will be able to go about among his colleagues with head erect and a grateful feeling that when the war came he was able to do his bit, and a big bit, for his country.

It is a glorious chance the young American surgeon is taking. He is going forth to meet, perhaps, the Great Adventure. He goes, joking it may be, as is the custom of our countrymen in time of danger, but with steadfast purpose in his soul and dauntless courage in his heart. He may return wearing the Red Badge of Courage, or he may find a resting place somewhere in France, but our prayers are with him. So ever, when humanity bleeds or danger threatens, may the doctor be first in the field!

CO-OPERATION BETWEEN THE PHYSICIAN AND SURGEON IN GASTROLOGY.

FINNEY, in his address at the recent annual meeting of the Medical Society of the State of New York (*N. Y. State Journal of Medicine*, May, 1917), strongly emphasized the need for efficient co-operation in the diagnosis and treatment of affections of the stomach, and brought out many truths in his

usual rugged and forceful style that could not fail to impress his audience with the fact that, for the average practitioner, playing a lone hand in these cases, is, or at least may be, a dangerous game. How thoroughly Finney practises what he preaches in this respect is indicated by his statement that he never operates upon a supposed stomach case without having first had it thoroughly studied and reported upon by a competent internist, or until he is satisfied that nothing more is to be expected from a continuance of medical measures. But, one may say, it is not always possible to obtain the services of a skilled internist for the study of these cases, especially in a country practice. Finney effectively disposes of this objection when he says: "It is equally true, a fact that should not be lost sight of, that questions of operative treatment of stomach diseases are not for the country doctor, who only does a little surgery of necessity, to decide, but for the thoroughly competent surgeon skilled in the care and treatment of such cases."

As Finney points out, every practitioner, whether general or special, must have been struck with the great frequency with which stomach symptoms usher in almost any affection; and that among the extraabdominal condition with which the stomach may show functional derangement are pneumonia, tuberculosis, brain tumor, the acute exanthemata, angina pectoris, arteriosclerosis, various disturbances of kidney functions, eyestrain, etc., while the same disturbances of normal function may be found with many intraabdominal conditions, as in the vomiting of pregnancy, appendicitis, intestinal obstruction of one sort or another, mesenteric thrombosis, acidosis, uremia, etc. These disturbances may occur in the absence of any organic trouble whatever with the stomach itself, while, in addition, the disturbances due to the many morbid conditions affecting the stomach, alone or coincident with disease elsewhere, come up for consideration. With disturbances of gastric function occurring under such manifold conditions, Finney calls attention to the fact that "in arriving at a definite diagnosis in any case of so-called stomach trouble the physician will not infrequently be called upon to go over in a general way the whole ground indicated above, and much more, before being able to discriminate between a case of real stomach disease and one in which the stomach symptoms, while prominent, constitute only a minor consideration, because secondary to some other pathological condition elsewhere in the body; and that a stomach case may, after careful consideration, prove to be an inflamed appendix, cancer of the rectum, brain tumor, gastric crisis of tabes, cholecystitis, cholelithiasis, or what not." It should also be remembered, however, that although the surgeon is admittedly dependent upon the internist for the interpretation of certain features of the individual case, the internist should not delay too long before seeking the advice of the surgeon in all cases where there is a possibility that operation may be necessary. This fact was very strongly emphasized years ago by Rodman, when he bitterly arraigned the physician who sometimes waited so long to make a positive diagnosis that the case had become inoperable.

The diagnosis of any given case of stomach trouble is not only not always easy, but sometimes extremely difficult, and at times actually impossible without exploratory incision; and perhaps even then the ultimate decision must rest with the pathologist. This, Finney thinks, is a rather humiliating confession to be obliged to make in these days, when our diagnostic ability, aided by the various laboratory tests, has reached such a high stage of development; and we would join in the plea for cooperation between the surgeon, internist, radiographer, and laboratory staffs, in order that the percentage of cases in which a definite, correct, preoperative diagnosis is made may be increased.

The great need for such cooperation has been well shown in certain series of studies, notably those of Cabot and Abrahams, that have been made with the idea of determining the percentage of diagnostic errors. One series, based on autopsy records, must have been particularly disconcerting to the internists and surgeons, whose conclusions, in many instances, were shown to have been far from correct. In considering the reasons for diagnostic errors, Abrahams' classification, quoted by Finney, affords much food for thought. He divides these into two groups: "(1) Social, due largely to the personal equation of the physician himself; and (2) clinical errors, due to (1) ignorance, (2) faulty judgment, (3) obsession, (4) failure to think automatically, (5) failure to think at all, (6) reluctance to accept responsibility, (7) inherent difficulties of the case, (8) incomplete examination." Concerning this, Finney says: "It is evident at once that if his analysis is correct some of these mistakes may be condoned and others not. Unquestionably, the first and last, ignorance and incomplete examination, are responsible for the majority of our mistakes, and these may be corrected. Indeed, all of them, except possibly those due to inherent difficulties in the case, may be overcome, and all the time, with our improved methods, this group is getting less and less." This latter statement is probably true for the larger medical centers and in those cases where the services of the expert internist and surgeon are enlisted, but we confess to a more pessimistic view when the diagnosis and surgical treatment of the case rest with the average general practitioner and the less experienced surgeon. Many an "exploratory" operation is done by embryo surgeons when the more experienced operator would require more definite indications for operative attack, or would hesitate to operate at all because of unfavorable concomitant conditions; for, as Finney says, "with added years and accumulated experience comes increased caution."

In view of the inherent dangers and difficulties

of stomach surgery, we would therefore strongly urge two things: First, that before a patient presenting stomach symptoms is advised to undergo the perils of operation the case shall be thoroughly studied by a competent authority, if available in the community in which he lives, and that when sufficiently skilled local practitioners are lacking he shall be referred, when possible, to the nearest medical center where such competence can be found. Second, that whenever possible, operation, if indicated, shall be performed by a surgeon who has had long experience in abdominal surgery and who is thoroughly competent to deal with the various complications that may be encountered, many of which perhaps cannot be diagnosticated before opening the abdomen. It is only by careful study at the hands of those trained in the diagnosis and treatment of stomach conditions that the percentage of error can be reduced to the minimum.

THE PHYSIOLOGY OF FOOD AND ECONOMY OF DIET.

THE question of food has been for some time one of great importance to the European nations at war, and it is now becoming an absolutely vital one. At the present time this country is not only concerned with supplying her own population with an adequate supply of food material, but England, France, and Italy, to a lesser extent, rely upon America to make up deficiencies in their home supply. Consequently, the food question, although not so acute as in Europe, is yet sufficiently serious.

Recently, a little book* has been published by Dr. W. M. Bayliss, Professor of General Physiology in University College, London, the object of which is to give scientific information on all questions related to food. Among the points dealt with is the quality of food required for mental workers. Bayliss draws attention to the fact that the energy value of the diet for a man engaged in mental work is sometimes given as the same as that of a man doing very light mechanical work. Now this is possibly correct, since, so far as we know, the actual consumption of energy in mental processes is not great. But the author goes on to say that there is another consideration which, in his opinion, should be taken into account. The oxygen consumed by an organ is an index of the exchange of energy therein, or an index of the food required by the organ. So far as experimental results go, it does appear to be the fact that the actual consumption of oxygen in the nerve centers is not great, but, on the other hand, it has to be supplied at a high pressure. This is shown by the fact that even momentary stoppage of the blood supply causes immediate unconsciousness, although the oxygen of the blood still remaining in the brain cannot have been exhausted. It is somewhat as if we had an electromagnet which does not need much current to actuate it, but, owing to the wire with which it is wound is of high resistance, and consequently a high voltage is necessary to drive even a small current through. Should the brain be an analogous case, it seems possible that although the actual consumption of food is not great, yet this food may require to be presented at a high pressure, and that to attain the high pressure it may be necessary to take a diet of an energy equivalent to that of moderate muscular work.

With respect to alcohol, Bayliss affirms that there is no benefit, from the food standpoint, to be derived from the use of alcohol, and this being the case, if there is likely to be any shortage of food, the first prohibition to be made ought surely to be of the use of food materials in distilleries and, to a lesser extent, in breweries. For the manufacture of alcohol as a solvent for explosives, materials unfit for use as food, such as bad potatoes, could be used. Moreover, Bayliss points out that nothing can alter the fact that there is a loss of energy in the change from carbohydrate to alcohol. If the barley thus used were consumed directly by man and cattle, the energy value obtained would be greater than if all the products resulting from its use in making beer were consumed. It is doubtless true that very little sugar is added, as such in the manufacture of beer, but the starch of the barley is converted into sugar in the process and part of its energy value lost by fermentation.

In connection with vegetarianism, Bayliss states that there is no special virtue in butcher's meat, and that vegetable foods, if properly chosen, can supply all that is necessary for a complete diet. The protein is not quite so easily digested, but in compensation more of the food can be taken. The conclusion to which the author comes is that a diet of purely vegetable origin cannot be safely made up until more is known concerning the properties of each food stuff.

One feature of the food situation in Great Britain referred to by Bayliss might be applied with equal force to the situation in this country. He lays stress on the fact that one of the most pressing needs at the present time is a control of the prices of food and a means of insuring equality of distribution. Many dealers in foodstuffs appear to think themselves justified in exacting as high a price as they can get their customers to pay. When the price of food is higher in Great Britain than in Belgium, and higher in this country than in Great Britain there is evidently something wrong.

*The Physiology of Food and Economy in Diet. London and New York, Longmans, Green & Co., 1917.

A PERSONAL CASE OF HOSPITAL GANGRENE.

THE statement that hospital gangrene no longer exists must not be accepted too literally. It does not exist as a contagious plague, nor does it occur in a severe form (the two doubtless go hand in hand), but not infrequently the French military surgeons mention a complication of wounds which agrees in essentials with the once dreaded scourge. Verdelet, in the *Gazette hebdomadaire des sciences médicales*

de Bordeaux for May 27, reports that on June 12, 1915, when he was dressing a boil on the neck some pus ran down on the back of his hand. Two days later a folliculitis appeared over the extensor tendon of the thumb at the metacarpophalangeal joint. This disappeared in three or four days. On June 19 he amputated in the thigh for purulent arthritis of the knee, and again pus came in contact with his hand. Next day there appeared at the site of the folliculitis a livid spot, and by night pain was marked, with constitutional symptoms, the sheath of the tendon having been infected. Lymphangitis was soon in evidence. The infection gradually spread to all the extensor tendons of the fingers. The systemic reaction was mild until June 27, when evidences of septicemia suddenly appeared. After free incisions in the dorsum of the hand these symptoms abated. By July 7 the condition was quiescent, the hand still showing infiltration; but at once a new focus appeared over the third metacarpal. A fresh incision gave relief until July 15, when another recrudescence appeared. The hand began to swell and its skin to redden, an incision scar reopened and the wound exhibited a false membrane characteristic of hospital gangrene. Hemorrhagic blebs appeared on all the fingers. A severe general reaction set in with chills, vomiting, and icterus. The gangrenous wound was at once cauterized with the paquelin, followed by spraying with Labarraque's solution and permanganate. But little change was noted for several days, when a favorable crisis set in—diaphoresis and diuresis, with fall of temperature and subjective improvement. The false membrane began to slough, revealing healthy granulations. The chief local treatment was the hot air douche. The wound cauterized and gradually infiltration disappeared from the hand, which, however, was left in a dystrophic condition. Its color was livid, the nails were deformed, the joints and tendons were stiff, and the muscles atrophic, those of the forearm and arm having shrunk in size. The period of disability lasted nearly a year.

A Wholly Unnecessary Law.

The physicians of this city were more or less disagreeably surprised and puzzled to receive on Saturday of last week a letter from the State Commissioner of Health inclosing sundry blank forms and ordering them to file on the preceding Tuesday an inventory of all the preparations or derivatives of opium at that time in their possession. Under separate cover was sent a copy of the law prescribing this inventory. The law is clumsily worded, but so far as one could make out from a careful perusal of it every physician in the State, having failed to file the inventory several days before he had heard of the necessity of so doing, has been guilty of a misdemeanor. The Commissioner calls the law one "governing the sale of habit-forming drugs," but the law itself specifies only "opium or any of the salts, alkaloids, or derivatives, or any compound or preparation of them." So it is a law governing the sale of only one group of the habit-forming drugs, and is in so far inadequate to prevent drug addiction; moreover, all its provisions and much more are fully covered by the Harrison law, and it is therefore useless. It merely adds to the annoyances of the physician, and cannot possibly affect a single addict who is not already under the restraint of the Harrison law. In addition to filing an inventory of all opium preparations in his possession, the physician must register with the State Commissioner of Health, pay a dollar, swear (legally) twice at 25c. per swear, and ever thereafter make out numerous order blanks, keep records of prescriptions, et cetera, repeating the registration and the swearing annually.

News of the Week.

No Infantile Paralysis.—The Board of Health has issued a statement to the effect that this city is apparently free from poliomyelitis this season. Last year at this time there had been 1900 cases of infantile paralysis reported since the beginning of the year, while so far this year only 77 cases have been reported.

Death Rate of New York City.—The death rate of this city last week was the lowest ever recorded in the history of the Health Department, being 10.36 for each 1,000 population. The death rate among babies under one year of age was 85 deaths for each 1,000 births for the period since January 1. During the corresponding time last year the rate was 93. Only ten years ago the death rate among babies was twice as great.

Dr. Leverett D. Bristol of Boston has been appointed first health commissioner of the State of Maine by Gov. Milliken.

Dr. William J. Mayo of Rochester, Minn., has been summoned to Washington to confer with the Government officials relative to the formation of a central medical staff in Washington, the purpose of which will be to obtain the best medical service for American soldiers while in the field.

"Drug King" Sent to Prison.—Convicted of operating a bogus sanatorium for drug users and of secretly importing heroin and other narcotics from Havana for distribution throughout the entire East, a man claiming to be a physician was recently sentenced here to two years and nine months in Atlanta Federal Prison and to pay a fine of $2,000.

Report on Transmittance of Poliomyelitis.—Dr. Hideyo Noguchi and Dr. Rokusaburo Kudo of the Rockefeller Institute for Medical Research, have undertaken to determine whether poliomyelitis is carried by flies and mosquitos. They report their results in *The Journal of Experimental Medicine* as follows: Of several hypotheses concerning the mode of conveyance of poliomyelitis that of direct contact appears to be the only one which stands on a substantial basis. Specimens of *culex pipiens* raised from the larval stage in water experimentally contaminated with an abundance of poliomyelitic virus were found to be incapable of causing the infection when allowed in large numbers to bite normal Macacus monkeys. Experiments with flies also show that it is improbable that the virus of poliomyelitis is taken up by fly larvæ and multiplied therein. Not only does the virus fail to multiply, but probably it is rapidly destroyed within the body of the insects. The notion that these non-biting flies may act as intermediary hosts or a

virus reservoir is not justified by evidence brought out in this present study.

Increased Street Perils.—During the last six months according to the report of the Police Commissioner, 12,284 persons have been victims of street accidents in this city, compared to 10,593 for the same period last year. In June there were 565 more accidents than during the same time last year.

Patent Medicine Men Victorious.—New York City patent medicine manufacturers have won an important decision over the Department of Health before the Appellate Division of the Supreme Court, which declared invalid the ordinance requiring the manufacturers of all proprietary remedies to register all the active ingredients of such remedies with the Department of Health. Such registration was confidential. Since the ordinance had not been ratified by the State Legislature it was open to attack on the ground of unreasonableness, according to the Court.

Aid for the Tuberculous in France.—The International Health Board of the Rockefeller Foundation Commission for the Prevention of Tuberculosis in France is about to put its plans into execution. The commission will be under the care of Dr. Farrand and Dr. James Alexander Miller will take charge of the phases of the work relating to medical relief.

Dr. H. S. Baketel of this city, a lieutenant in the Medical Reserve Corps, U. S. A., has been promoted to the rank of major.

The War Babies' Cradle.—Mrs. F. A. Clark, president of the American Committee of the War Babies' Cradle, has issued an appeal for funds to provide care for poor Frenchwomen in childbirth. They are mostly soldiers' wives and many of them are in the region of northern France desolated by the Germans. Contributions may be sent to Mrs. Jules Bache, 350 Madison Avenue, New York City.

Obituary Notes.—Dr. JAMES A. JONES, assistant city physician of Lynn, Mass., died at his home on July 3, of heart disease, aged 53 years. He was graduated from the University of Vermont College of Medicine, Burlington, in 1906, and was a member of his County and State Medical Society.

Dr. JAMES M. TUBB, a graduate of the Memphis Hospital Medical College, Memphis, Tenn., in 1893, died at his home at Bessemer, Ala., after a long illness on June 21, aged 66 years.

Dr. ROBERT C. BLACK, a graduate of Rush Medical College, Chicago, Ill., in 1858, died at his home in Gainesville, Tex., on June 22, very suddenly of heart disease, aged 85 years.

Dr. WALTER L. PURSSELLEY, a graduate of the Missouri Medical College, St. Louis, in 1897, died at his home in Springfield, Mo., on June 21 of apoplexy, aged 51 years.

Dr. WILLIAM B. EZELL, a graduate of the Atlanta Medical College, Ga., in 1861, died at his home in Brunswick County, Va., at 80 years of age. He served both as a private and lieutenant in the Confederate army during the Civil War, participated in several battles and was confined in the prison at Richmond for a term of weeks.

Dr. ALEXANDER C. DICK died at his home in Sumter, Va., on June 27, after a long illness, at 56 years of age. He began his medical education at the University of Virginia, but later received his diploma from the Medical College of the State of South Carolina, Charleston, in 1889.

Dr. FRANCIS M. RIDLEY, a graduate of Tulane University of Louisiana School of Medicine, New Orleans, in 1880, died at his home in LaGrange, Ga., on July 7, aged 63 years, after an illness of several weeks. He was president of the State Board of Medical Examiners, chief surgeon for the Atlanta and West Point railroad, and a member of both County and State Medical Society.

Dr. FRANK B. REAGOR, county health officer, died suddenly at the home of his brother, Dr. L. T. Reagor, at Shelbyville, Tenn., on June 29, aged 57 years. He was graduated from the University of Tennessee, Medical Department, Memphis, in 1891, and was a member of both County and State Medical Society, and a fellow of the American Medical Association.

Dr. GEORGE T. MCWHORTER died at his home in Riverton, Ala., after an illness of over two years, on June 29, aged 67 years. He took an active interest in the politics of his county and while in the State Legislature he endeavored, though unsuccessfully, to establish a colony for epileptics.

Dr. GEORGE E. WALTON of Daytona, Fla., died at the home of his son at Terre Haute, Ind., during the third week in June after an illness of several years, aged 77 years. He was graduated from the Bellevue Hospital Medical College, New York, in 1864, and served as a surgeon in the Union army during the Civil War, and when President Lincoln was assassinated, he was one of the first physicians to reach his side.

Dr. ALBERT V. VEAZIE, of New York City, a graduate of the Tulane University of Louisiana School of Medicine, New Orleans, in 1908, died at the home of his father, Dr. Henry A. Veazie, in New Orleans, on June 30, from Bright's disease, aged 37 years. He studied for the stage, later entering medicine and for several years before practising in New York, followed the sea as a ship's surgeon.

Dr. NICHOLAS C. SCHILTZ, for the past 19 years an instructor in the Drake University Medical School, Des Moines, died at his home in the city from cancer on July 1, aged 51 years. He was graduated from the Rush Medical College, Chicago, in 1892, and was a member of his County and State Medical Society, and a fellow of the American Medical Association.

Dr. JOSEPH L. ABT died at his home in Chicago, Ill., on June 30, after a prolonged illness, aged 52 years. He was graduated from the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1892 and from the University of Illinois, College of Medicine, in 1893, and was a fellow of the American Medical Association.

Dr. JAMES F. SPELMAN died at his home in Anaconda, Mont., from Bright's disease, on July 1, aged 49 years. He was graduated from the University of Pennsylvania in 1890 and received an appointment as house surgeon at the hospital in Harrisburg, Pa. He then began to practise in Anaconda and in 1899 took a special course in surgery at St. Bartholomew's Hospital, London. He was a fellow of the American College of Surgeons and also a fellow of the American Medical Association, and one time president of the Montana State Medical Association.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HALF A MILLION DOLLARS FOR THE RED CROSS FROM AUSTRALIA—THE FRANCHISE FOR SOLDIERS AND SAILORS—FUNERAL OF VICTIMS OF THE BABY-KILLERS—MEDICAL OFFICERS OF HEALTH—ACRIFLAVINE—HOSPITAL SUNDAY.

LONDON, June 23, 1917.

THE joint war committee of the Red Cross Society and the Order of St. John has just received through the Australian branch of the Red Cross the sum of £100,000 contributed by the people of Victoria for the Red Cross funds. This is the magnificent first result of an appeal organized throughout the State of Victoria by Lady Stanley, wife of Sir Arthur Stanley, governor and president of the Victorian division of the Australian Red Cross. The appeal was launched early in May, and the response to it was immediate and enthusiastic. The earliest donations included 18 of £100,000 each; the list on the opening day reached £34,370 and within a fortnight Sir Arthur and Lady Stanley were in the happy position of being able to announce that they had received the sum of £70,000, which grew rapidly to the figure of £100,000 now remitted as a preliminary contribution to the Red Cross headquarters.

The Senate of the London University has elected Sir Cooper Perry as vice-chancellor, to succeed Sir Alfred Pearce Gould.

The Earl of St. Germans, who holds a captain's commission in the Dragoons, has been wounded. Born in June, 1890, educated at Eton and Sandhurst, he has been mentioned in dispatches and awarded the Military Cross during the war.

The Home Secretary has brought before the House of Commons a remodeled clause giving votes to soldiers and sailors. Every man in active service and on full pay is to have his right to vote for the place of his home or for the place where he has obtained his six months' residential qualification. It will be the duty of the registration officer to inquire as to the persons entitled to be registered, and the soldier or sailor will not have to claim the vote.

At the funeral service for the 15 child victims of the air raid on the 13th a message from the King was read, showing how he and the Queen were thinking of the mourners and praying that they might be blessed with God's help and comfort in their sorrow.

The Royal Medical Benevolent Fund is now called upon as a result of the war to deal with the cases of many widows and children who in happier times would have needed no assistance. At the last committee meeting no less than 20 cases were under consideration and £163 was granted to 16 of the applicants. The guild is glad to receive second-hand household linen and clothing. The clothes most needed are those suitable for boys and girls working in offices, or for women or old men.

At a meeting of the N. W. branch of the Society of Medical Officers of Health a letter was read from Prof. Sheridan Delépine, director of the Public Health Laboratories of Manchester University, who had been invited to speak but was unable to be present. Though not personally concerned with the administrative duties of such offices, he had during the last 25 years, owing to his official position, had many opportunities of observing the loss of time, money, and power for good, resulting from the present uncoordinated and sometimes antagonistic state of the various departments interested directly or indirectly in public health.

The medical research committee have written to the lay press to correct statements based on misapprehension of the situation in regard to the properties and the supply of acriflavine. The unique properties of this substance were known several months ago, although only moderate quantities were obtainable for a considerable time. The medical research committee seem to have assumed responsibility for the supply of the drug, but they have offered no explanation of the delay in its production which has been complained of, and on account of which it has been urged by some that the Government should undertake the supply.

Hospital Sunday is the day after to-morrow. So it may not be amiss to report that the claims of those institutions are as urgent as ever; for some three years they have borne the burden of the loss of doctors, nurses, and staff, as well as the increase of cost all round, maintaining their great work for the sick poor, besides caring for some 150,000 of our wounded. The in-patients are now about 12,000 occupying beds. The out-patients number about 17,000. Our hospitals have always been a cause of reasonable pride, which will be accentuated when the history of the war records, as it must do, that they sustained a principal part in the system whereby the enemy was met and defeated.

1. A Report of a Service with the First Harvard Surgical Unit at a British Base Hospital, with the End Results of the Cases One Year Later. Channing C. Simmons.
2. Ascending Lymphogenous Renal Infection. Daniel N. Eisendrath and Oscar T. Schultz.

2. Ascending Lymphogenous Renal Infection.—Daniel N. Eisendrath and Oscar T. Schultz state that they have made an attempt to study the route of infection of the kidney which takes place in an ascending direction along the interstitial lymphatics of the ureter. They have felt for some time that the older view of infections ascending from the bladder to the kidneys along the lumen of the ureter must be abandoned, except in cases of complete obstruction of the ureters. In two series of experiments carried out a total of thirty-seven female animals were used, eleven rabbits and twenty-six dogs. The organisms employed were *Bacillus coli, Staphylococcus aureus* and *Bacillus proteus*. Attempts were made to imitate conditions clinically in cases of ascending renal infection in the human being, by making an emulsion of sterile salt solution and scrapings of four agar slant cultures, which was injected into the bladders of the female dogs and rabbits through a sterile silver cannula of very narrow caliber. Caution was taken as to presence of any previous infection and the animals were anesthetized with ether; every precaution was also taken to avoid any injury to mucosa of bladder and urethra. The animals were killed at varying times with strychnine. Of the eleven rabbits, six showed involvement of the ureter, five of the pelvis, and six of the kidney. The pathogenic organism injected was recovered from the bladder five times; from the kidney twice. Of the twenty-six dogs used, twenty-one showed ureteral involvement, sixteen pelvic involvement, and thirteen

lesions of the kidney. The organism injected was recovered from the bladder twelve times and from the kidney five times. Seven dogs were examined by the same method as controls. One of these showed the same type of lesion in the ureter and pelvis. Microscopical investigation of the tissues was also carried out. Eisendrath and Schultz further state that (1) anatomical studies have demonstrated the presence of an anastomosing network of lymphatics in the wall of the bladder and of the ureter, communicating above with a similar lymphatic network in the renal pelvis and parenchyma. At its lower end this system communicates also with the lymphatics of the pelvic structures, in both the male and female. (2) Infections of the bladder or lower ureter may reach the renal pelvis or the kidney, either by way of the lumen of the urinary tract or by way of the mural lymphatics. (3) Experimental and clinical evidence indicates that almost complete obstruction to the free passage of urine is necessary for ascent of infection by way of the lumen of the urinary tract. (4) Experimentally they have shown that infection, set up by the simple introduction of bacteria into the bladder without injury or without obstruction, may pass upward by means of the interstitial lymphatics of the ureter. (5) The degree of involvement following the introduction of bacteria into the bladder depends upon the virulence of the organism and upon the susceptibility of the animal. The subsequent tissue reaction may remain limited to the bladder and ureter, it may pass upward to the tissues of the renal pelvis, or even the parenchyma of the kidney itself may become involved. (6) When the kidney tissue is involved in ascending infection brought about experimentally, as described, the path of travel is from the subepithelial tissues of the pelvis to the kidney by way of the inter-tubular and perivascular lymphatics. (7) From the kidney the perirenal tissues may become involved through the capsular lymphatics, which anastomose with those of the cortex. (8) The experimental evidence indicates that, in cases of pyelitis and pyelonephritis in the human, secondary to infection of the bladder, the lymphatics constitute the most important course of upward travel of the infection, especially in those cases where there is no hindrance to the urinary outflow. (9) Pyelitis and pyelonephritis, not secondary to cystitis, may also be the result of lymphatic transport of infection from the pelvic organs in the male and female, and from the lower intestinal tract.

5. Larva Migrans on the Mexican Border. Charles Perley Gray.
6. The War and the Nervous System. Smith Ely Jelliffe.

5. Larva Migrans on the Mexican Border.—Charles Perley Gray gives the results of his experiences in the treatment of cases of larva migrans from the bot fly in men in the Federal service on the Mexican Border during the summer of 1916. The histories were practically the same. Following a test march, called the ten day hike—100 miles—in August, a large number of men complained of an intense itching of various parts of the body. The temperature at the time was high, ranging from 100° to 120° F., registering one day as high as 141, and on general examination the condition was considered to be prickly heat, since in many cases the eruption appeared on the back underneath the pack which each man carried. The condition did not yield to the ordinary treatments and the men suffered from lowered vitality due to loss of sleep as a result of their condition. A few days later, close examination revealed small vesicles, from which serum exuded when they were pricked, profuse in number, but segregated in small groups with patches of clear skin between them. On watching the skin closely, however, it was noticed that within twenty-four hours after these vesicles were rubbed by scratching, small serpentine furrows would develop, at the end of which another vesicle would appear, and from the tract itself sometimes serum appeared. These vesicles would at times, following various treatments, lie dormant for four or five days without itching or symptoms of discomfort; then suddenly they would begin to itch, scratching would occur and another serpiginous tract would appear. The top vesicle would be broken by the scratching, the serum exude and spread over the skin, a tiny furrow would slowly spread in a given direction, and in twenty-four or thirty-six hours another vesicle would appear at about an inch distant, followed in another twenty-four hours by a repetition of the process further on, until the condition spread all over the body, sometimes on the arms and legs as well. Macroscopically the lesions showed no parasite; under the microscope but once could there be detected anything resembling a living parasite. It had a threadlike appearance with a slight joint, like a lobster's claw, on the end. This was invisible under the magnifying glass, and the pathologist was not sure that it was not extraneous matter. The only treatment that proved effective was to paint the vesicle and burrow with a fine brush with strong carbolic acid, ninety-five per cent., until the tissue turned white, and then to paint the surface over with ten or twenty per cent. tincture of iodine. Only the vesicle and burrow were touched. This was followed up the second day, protected by a dry, sterile dressing, the patient allowed to rest, and carefully watched for recurrence. Sometimes one treatment would suffice, but where the lesions were extensive several sittings were necessary. Gray's theory is that the condition was caused by some form of animal or vegetable parasite. It was traced back to a ranch where all the men later affected camped in an old corral infested with flies and horse manure. Gray treated over one hundred cases in two regiments during a period of over three months, though many forms of treatment were tried before the most efficacious one was worked out. The majority of the cases at first stopped immediately, lay dormant for a week or two, only to break out anew at the end of that time.

9. A Report of the Use of Dichloramin-T (Toluene-Parasulphone-Dichloramin) in the Treatment of Infected Wounds.—H. D. Dakin, Walter Estell Lee, Joshua E. Sweet, Byron M. Hendrix, and Robert G. Le Conte report on their search for the perfect germicide. To be such, two simple requirements must be met. It must kill all parasitic life, while causing no harm to any cell of the living body. The problem has been partially solved for certain groups of infective agents belonging to the lower forms of animal life. The bacteria have shown a greater resistance to lethal agents than is possessed by the cells of the animal body, and therefore the great problem of surgery, the prevention and control of bacterial infection, remains but partially solved.

The demands made on surgery by the extensive suppurating wounds of modern warfare have reopened the question of treatment and made necessary a further search for an agent which would meet the requirements of a perfect germicide. In military surgery the problem has distinctly been one of treatment of infection, antisepsis. Skin irritation entered into the use of many of the solutions used in cleaning up wound infections, especially the chlorine preparations. This group of experimenters have produced the following and state that in comparing the practical surgical value of dichloramin-T with aqueous hypochlorite solutions in the treatment of infected wounds, which in spite of many serious objections has given such promising results, they believe that their laboratory and clinical findings thus far warrant the following statements: (1) Dichloramin-T is a nonirritating synthetic germicide, and corresponds to the antiseptic chloramine substances found in minute quantities when nascent chlorine of the aqueous hypochlorite solutions is brought into contact with the exudate of suppurating wounds. (2) Dichloramin-T can be used in strengths of from twenty to forty times greater than is possible with the hypochlorites and in an oily solution which makes possible the slow elaboration of the germicide over a period of from eighteen to twenty-four hours instead of a rapid disappearance in from thirty minutes to one hour as with the hypochlorites. (3) Its use is as simple as the application of the tincture of iodin, and they can see no reason why it cannot be used to replace iodine as a primary dressing. In their experience it is just as effective as a germicide, and is without the destructive effect on the tissue cells. They have had the opportunity of using it in this way at the primary operation in seven wounds involving soft tissues, tendons, joints and bones and have not failed to have primary union. One case, a compound fracture of a metacarpal with severed extension tendons, did not receive treatment until three hours after the injury. (4) The chlorine in dichloramin-T, as in the hypochlorites, has the power of dissolving dead tissues. Hemorrhage, therefore, must be stopped by ligation, else the clot will dissolve and secondary hemorrhage may follow. (5) One should not depend on a chemical agent to perform, in the treatment of suppurating wounds, for that which can and should be done quickly and thoroughly by mechanical means. Neither chemistry nor bacteriology can or should be expected to replace the mechanics of surgery. At the best these chemical germicides can react only on the bacteria with which they actually come in contact which means a very superficial process. Therefore, at the primary operation all infected tissue, foci and devitalized tissues must be removed when possible by surgical procedures. Finally, adequate drainage, dependent if indicated, must be provided. They have seen two cases of skin irritation after several weeks of continuous use. It is similar to the eruption of ivy poison, and may be due to the eucalyptol.

5. Freud's Psychology of the Unconscious. W. H. R. Rivers.
6. Salvarsan and Intramine with Reflections Upon Chemotherapy. J. E. R. McDonagh.

5. Freud's Psychology of the Unconscious.—W. H. R. Rivers considers it possible, even probable, that the practical application of Freud's theory of the unconscious in the domain of medicine may come to be held as one of its least important aspects, that it is perhaps in other branches of human activity that its importance will in future be greatest. Rivers' own belief in the value of Freud's theory of the unconscious as a guide to the better understanding of human conduct is not so much based on clinical experience as on general observation of human behavior, on evidence provided by the experience of friends as well as observations of his own mental activity, waking and sleeping. The feature which makes Freud's theory noteworthy is his scheme of the nature of the opponents in the conflict, and of the mechanism by which the conflict is conducted. Another concept characteristic of Freud's psychology is that of dissociation, but the idea is older than Freud and forms part of systems of psychology very different from his. The special merit of this theory in this respect is that it provides a psychological theory of dissociation, of the factors upon which it depends, and of the processes by which its effects can be overcome. According to Freud forgetting is an active process, not negative as heretofore taught. In considering the Freudian theory of the unconscious with reference to the neuroses of the war, Rivers states that fate seems to have presented an unexampled opportunity at the present time for the testing out of these theories. His opinion is that so far as the theory and clinical methods founded upon it are concerned, both are largely doomed to disappointment, since they seem to be inadequate as a means of explaining and treating those disorders for which the theory was originally designed. Certain features of the situation must be taken into account before any conclusion can be accepted. First, it must be noted, that while the proportion of the population from which cases of warstrain are now being drawn is very large, it is not wholly representative, but has been selected, perhaps in a rough way, by the medical examination preliminary to enlistment. Another and more important reservation depends on the fact that warfare tends to produce states of anxiety and apprehension so deep-seated and far-reaching that they obscure causes of a different kind. Cases arising out of the war do not for this reason furnish satisfactory material whereby to test the truth of the Freudian position. Persons who break down under the strains of ordinary life in whom other states are not hidden by the overpowering emotional conditions arising out of modern warfare provide material which shows far more readily the influence of unconscious factors of the kind which are held to be so important by the Freudian school. Even when the reservations are taken into account, there remains singularly little to support the Freudian position in the form in which it is usually presented to us by its advocates. Rivers' experience shows this to be particularly true in regard to the part played by sexual experience in the production of the functional disorders arising out of the war. Those forms of paralysis and contracture, phobia and obsession, regarded by the Freudians as the result of repressed sexual tendencies occur freely in persons whose sexual life seems to be wholly normal and commonplace, singularly free from those sexual repressions which are so frequent in modern civilization. Certainly, if results are any guide, the morbid states disappear without any such complexes having been brought to the surface, while in other cases the morbid states persist in spite of the discovery of definite complexes, sexual or otherwise, going back to times long before the war. Denial, however, of the validity of Freud's theory of the unconscious in the form currently held by its adherents as the means of explaining nervous and mental disorders is something very different from the denial of the validity of this theory altogether. While the Freudian types of mental and nervous cases are few among the cases arising out of the war, there is hardly a case which this theory does not help us the better to understand—not a day of clinical experience in which this theory may not be of direct practical use in diagnosis and treatment. While the results of warfare provide little evidence in favor of the production of functional nervous disorders by the activity of repressed sexual complexes, Rivers believes that they will be found to provide abundant evidence in favor of the validity of Freud's theory of forgetting, the most striking and characteristic feature of his psychology. Rivers' shows that with reference to line of treatment used in the neuroses of war, the Freudian plan of freely discussing the painful experience and an attempt of readjustment by the individual, who has so suffered, carries out the practical side for good results, in many cases, rather than the generally accepted plan of attempted dissociation, of repression of the painful experience. Rivers concludes by stating that Freud's theory of the unconscious should appeal to the physician in that it provides him with a definite working scheme of influences, which he has long known to be active in

the causation of mental disorders and of bodily disorders traceable to mental factors. The great merit of Freud is that he has provided us with a theory of the mechanism by which this experience, not readily and directly accessible to consciousness, produces its effects, while he and his followers have devised clinical methods by which these hidden feactors in the causation of disease may be brought to light. Freud's psychology of the unconscious provides a consistent working hypothesis to aid in attempts to discover the rôle of unconscious experience in the production of disease. As it now stands the scheme is but a partial truth and will suffer many modifications with further research, but Rivers believes that it aims in the direction of the truth.

British Medical Journal.

1. The Development of British Surgery in the Hospitals on the Lines of Communication in France. George H. Makins.
2. On Some Anaerobes Found in Wounds and Their Mode of Action in the Tissues. Herbert Henry.

2. On Some Anaerobes Found in Wounds and their Mode of Action in the Tissues.—Herbert Henry states that the literature on the anaerobes is beset with so many contradictory statements that it is impossible to construct from it an accurate account of the reactions of even the better known organisms. Experience has shown that this confusion is due almost entirely to the investigation of impure cultures, for, with the establishment of a more exact and rigorous technique, the features of individual species are found to become more clearly defined, and previously existing discrepancies tend to disappear altogether. All the anaerobes isolated from wounds are probably fecal in origin. They give vigorous fermentation reactions in the presence of organic material, and according to their biochemical activities they may be divided into two main groups—the saccharolytic group and the proteolytic group. The members of this first group vigorously decompose a variety of carbohydrates with the production of acid gas, but they are only feebly proteolytic. The group comprises: (1) *B. welchii.* (Synonyms: *B. aërogenes capsulatus* of Welch and Nuttall; *B. perfringens* of Veillon and Zuber; *B. phlegmonis emphysematosae* of Fraenkel. (2) *B. tertias.* (Synonyms: *Bacillus Y* of Fleming; *B. von Hibler IX* or *B. rodella III* of Robertson. (3) *B. fallax* of Weinberg. (4) *B. aërofetidus* of Weinberg. (5) *B. oedematicus* of Weinberg. Pasteur's *Vibrion septique* would seem to belong to this group, but it is omitted because there has been as yet no opportunity of establishing its characteristics. The proteolytic group comprises (1) *B. sporogenes* of Metchnikoff. (2) *B. histolyticus* of Weinberg. (3) *B. putrificus coli* of Bienstock. (4) *B. cadaveris sporogenes* of Klein. (5) *B. tetani* of Nikolaier. The individual members of this group digest protein very vigorously, but have a restricted range in the matter of carbohydrate fermentation. The production of a gaseous cellulitis in the tissues surrounding a wound is practically certain evidence of anaerobic infection, although it must be noted that the infiltration of gas may often out-distance the microbic invasion in the tissues. It is not uncommon to find no microscopical or cultural evidence of organisms in the edema fluid taken from crepitant subcutaneous tissues at some distance from the wound. Another feature of anaerobic growth is the necrosis it produces in the invaded part. Quite apart from wounds which show these clinical manifestations, the majority of open wounds treated at a base hospital in France give cultural evidence of the presence of anaerobes. Out of 100 open septic wounds of all grades of severity examined at intervals of from two to twenty-two days after the receipt of the injury two-thirds showed the presence of *B. welchii*, and almost one-half showed the presence of *B. sporogenes*. It is unusual to find only one anaerobe in a wound. In the vast majority of cases the anaerobe infection is a mixed one, the most frequent combination being *B. welchii* with *B. sporogenes*. In contradistinction to these open wounds, Henry found that out of 500 specimens of hemothorax fluid examined from thoracic injuries, which were considered as closed wounds, 195 proved to be septic and 44.6 per cent. of these were infected with anaerobes. Here again, *B. welchii* is the most common infecting anaerobe, and the combination of this organism with *B. sporogenes* is frequent. The anaerobes tend to remain localized to the tissues during life, and it is only seldom that they can be found in the circulating blood. On the other hand, cases have been recorded of socalled metastatic gas gangrene in which anaerobes have developed in some position at a distance from the infected tissue. Henry states that the pathological processes in an anaerobe infected wound as being characterized by two main features—the production of gas and the death of tissue. Each of the two main groups of anaerobes above defined has its share in these processes, and the successive stages by which an anaerobe infection develops may be thus summarized: (1) The initial trauma in determining the death of tissue establishes a focus for growth. This is characterized by the latent period, which precedes any obvious clinical signs of anaerobic infection. (2) The first active phase of anaerobic infection consists in the development of the rapidly growing saccharolytic organisms, of which *B. welchii* is the chief. It is because of the richness of muscle in fermentable carbohydrate that this tissue provides such favorable conditions for the growth of organisms of the saccharolytic type. Their development results in the production of acid and gas. The gas accumulates first in the muscle and reaches the subcutaneous tissues by escape from the muscle. The pressure produced by gas and also by inflammatory edema fluid leads to an anemic condition in the tissues surrounding a wound, and this change initiates the second active period of anaerobic invasion. The muscle in the saccharolytic period is of a brick-red color. The second phase of anaerobic infection in a wound consists in active proteolytic digestion. This is characterized by death and digestion of the tissues. The process is accompanied by the formation of sulphuretted hydrogen and of volatile substances, which give the penetrating putrefactive odor so typical of the later stages of infection. The previously red muscle becomes soft and diffluent. It may be stained black by a sulphide of iron formed by the interaction of sulphuretted hydrogen with the iron released from broken-down hemoglobin. The toxaemia which develops at this period results from the absorption of toxic substances produced in the breaking down of the protein molecule, and cannot be attributed to the acid which is formed in the breaking down of the carbohydrate molecule. The final phase is that of successful bacterial invasion of the blood stream. It occurs in most cases just at, or immediately preceding, the death of the individual.

La Presse Médicale.

June 4, 1917.

The Severe Form of Trench Foot.—Chauvin refers to the three conventional types of this lesion based on degree of severity. The third degree is characterized by sloughing, and it is much less known in literature than the milder forms. It is sometimes termed pseudocongelation. But since the winter of 1917 we know of a fourth degree—a veritable gangrene in bulk, which often involves the entire foot. An inflammatory element is present and swelling may be in evidence as high as the knee. A general reaction coexists, the sepsis which attends congelations. Such forms may have no premonitory symptoms; only a trench foot of the mildest degree may at first be present. In fact, there may only be the usual subjective symptoms. This insidious onset, however, is the exception. As a rule edema marks the début of this severest type and the whole leg may swell. Pain may be associated. Any one of the three classic stages of severity may have first developed in the integument. The massive gangrene develops from the second to the fourth day. The distinction between the true and pseudocongelation is not clear for the author admits that the term "gelure" is the only one to use for gangrenous trench foot despite the points of difference between the two. If this form of trench foot is the same as a freeze of the third degree, an elaborate special description would not be required. In one type of gangrene the indications are local only. Should the entire foot be sacrificed by a

tibio-astragalus separation or will a Chopart or Lisfranc suffice? Should be amputate early or be governed by lines of demarcation? Temporizing is dangerous, for if patient is infected amputation will not save him; moreover, it is useless because of the probability that a higher amputation will be required. In his most recent cases based on early experience, the author may see fit to do a precocious high amputation to prevent death from threatened sepsis.

Duodenal Tubage.—Romme speaks approvingly of analysis of the duodenal secretions as obtained by tubage, as having displaced the older crude tests of Sahli and Schmidt and the oil breakfast. The use of the duodenal sound for this purpose was introduced by Einhorn and Gross in 1909-1910. In 1911 Hess, an American, reported its successful application in children with a soft rubber catheter. For adults the author prefers the heavy tube of Gross in as far as it is the most readily introduced. Fluoroscopic control is of great aid. The technique of White of Boston is described in full; any orderly can readily master its application. This physician did not see a single untoward result in 90 tubages. His results of analyses do not tally with those of Einhorn because different reagents are used, those of White all being extremely sensitive, tending to show that the three classes of enzymes in the duodenal secretion are in a constant state of fluctuation. Classifications based on amounts of enzyme present do not, therefore, appeal to White. Duodenal alimentation as introduced by Einhorn and developed by the latter and Morgan has also given brilliant results at White's hands and is destined to supplant rectal feeding for certain conditions. As White began tubage as a sceptic his warm approbation of its diagnostic and therapeutic efficacy is the more sincere.

Correspondenz-Blatt für Schweizer Aerzte.

April 7, 1917.

One-Minute Heart Death from Adrenalin Insufficiency.—Steiger's remarkable paper was briefly noted in the editorial columns of the MEDICAL RECORD some weeks ago. The article appears in full in the above number, and one of the author's four cases may be reproduced in detail. Patient, a man of 42, was admitted to the medical clinic of the Zürich University for supposed cardiac insufficiency. There was a history of lues, for which he had been treated 3 years before. Eight years ago he had suffered from a contusion of the spine with resulting curvature. On examination a kyphosis was found at the junction of the cervical and dorsal vertebræ. The skin of the face and neck was deeply pigmented, with a sharp line of demarcation at the collar of the undershirt. The same distinction was seen on the forearms. The skin of the penis and scrotum exhibited dark pigmentation. Aside from these anomalies the patient's condition was fairly good, as shown by numerous tests. The tuberculin reaction was negative. Low blood pressure alone—95 diastolic—was an unfavorable sign. Two days after admission, Professor Eichhorst made a diagnosis of Addison's disease. Next day the patient, who rose at 10 A. M., got into an excited argument with some relatives. He walked up and down and gesticulated. At 11 he returned to bed for a blood test. Suddenly he called out that he could not see and collapsed, falling as if struck by lightning, pulseless. As he was still breathing artificial respiration was instituted, but breathing ceased in 70 or 80 seconds. Autopsy showed that the coronary arteries were sound. Both adrenals were the seat of extensive tuberculosis. A study of the heart, in addition to the state of the coronaries, showed fully competent aortic valves. The diaphragm was high. There was slight hemorrhagic pericardial effusion. The auriculoventricular valves and their cords of both sides were thin and delicate. The myocardium, brownish red, was not notably softened.

Eclampsia without Convulsions or Loss of Consciousness.—Chatillon states that in 1913 but thirty-one cases of eclampsia without convulsions were on record. He has been able to increase this total to forty-two, including a personal observation with autopsy. The symptomatology of these cases shows much variation. In certain of them consciousness was retained. While the number of cases is not mentioned, the diagnosis is not always made before autopsy. Among wrong diagnoses have been acute and chronic nephritis with uremia, internal hemorrhage, gas embolism, and some form of poisoning. It is indeed almost impossible to make a final diagnosis. However, today such cases should be promptly recognized as examples of toxemia of pregnancy and doubtless the number of socalled cases of eclampsia without convulsions could be notably increased from this material. The author's patient was a primipara. Gestation had gone on to term without trouble. When first seen labor was in the expulsive period. After an injection of pituitrin the child and placenta were expelled. The infant was seen to be pulseless. Artificial respiration was without response. The mother five minutes after delivery was seen to turn pale with rapid, feeble pulse. There was no evidence of internal hemorrhage. She lived an hour and a half, during which she made no real response to treatment. The liver was the seat of extensive hemorrhages and to the microscope it was a typical eclampsia liver.

Hospitalstidende.

April 11, 1917.

Raynaud's Disease.—Schou describes a personal case of this affection of which over 300 examples have now been reported. Long known to be in part a disease of syphilitic origin, the recent advances in syphilography make it urgent to study every new case from this viewpoint even if Wassermann and treatment test prove negative. The author's patient, a man of 37, denied syphilis throughout, while his mother appears to have suffered from dead fingers and cold extremities. The Wassermann, however, was positive. Owing to the severity of the case, which was at first purely a surgical one, requiring intercarpal amputation of the left hand and several finger amputations on the right hand, the question of etiology was not at first of paramount importance. The patient was later placed on iodide of potassium without apparent benefit. He was then given an inunction cure and neosalvarsan by intravenous and intramuscular routes. The Wassermann remained unaffected. There was no hemoglobinuria at any time, but hematuria was present. Despite the suspicion of syphilis in Raynaud's disease, not much over 10 per cent. of this coincidence has been recorded. Of thirty-eight probable cases nearly all were seen before the introduction of the Wassermann test. The author makes three categories. Certain Raynaud's disease in syphilitics, 14 cases; doubtful (ditto), 8 cases; Raynaud's disease due to syphilitic arteritis, 16 cases (total, 38). The author's bibliography shows that he has consulted only six books or journal articles since the Wassermann has come into general use and only one since 1912.

Addison's Disease in a Child.—Rutelli saw a case in a girl aged ten years. The course was atypical and the diagnosis was made solely by exclusion.—*Pediatria.*

Objective Manifestations of Indigestion.—Pron enumerates relaxation of the abdominal wall which indicates a similar relaxation of the stomach; induced splashing after eating (splashing in an empty stomach means dyspepsia of long duration), and the sign of Leyden (dilatation of the pupil on pressure over the epigastrium).—*La Presse Médicale.*

Protein Nourishment and Reproductive Power.—Grumme asserts that defective production of milk and eggs during the present war is due directly to fodder poor in albumin. If geese are fed on potatoes 90 per cent. of eggs remain sterile, *i. e.* cannot be fertilized. But if cereal grains or bran be added to the potato diet this deficiency is at once remedied.—*Muenchener medizinische Wochenschrift.*

Elderly Primiparæ.—L. Meyer denies that in women in their thirties the birth tract is rigid, or at least he claims that there is no proof of such an assertion. Not every elderly primipara has a long labor. A distinction must be made between women who have been sterile in early married life and those who have married late in life. It is in the latter class only that we expect dystocia.—*Zentralblatt für Gynäkologie.*

Book Reviews.

CLINICAL BACTERIOLOGY AND HEMATOLOGY for Practitioners. By W. D'ESTE EMERY, M.D., B.Sc., Lond., Director of the Laboratories and Lecturer on Pathology and Bacteriology, King's College Hospital, London. Fifth Edition. Price, $2.75 net. Philadelphia: P. Blakiston's Son & Co., 1917.

EMERY'S work was prepared chiefly for the practitioner who had had little or no training in bacteriology and hematology and takes up the subjects of chief importance in a somewhat elementary fashion according to that idea. The present new edition shows but few changes from the fourth edition. The method of McIntosh and Fildes for the Wassermann reaction is included on account of popular demand. The work has been but slightly enlarged by the addition of new material. It is well suited to its purpose, but the demand for it should grow increasingly less as the profession comes gradually to be made up of men who have had the mentioned special training. For men who have had such training the work will necessarily seem rather inadequate in many ways, but for the beginner it will probably have a good deal of value.

LOCALISATION ET EXTRACTION DES PROJECTILES. Par L. OMBRÉDANNE ET R. LEDOUX-LEBARD. Prix, 4 francs. Collection Horizon. Paris: Masson et Cie., 1917.

THIS valuable work is somewhat larger than the average of the Collection Horizon, comprising about 350 pages, much of which is in fine print. There are 225 figures in the text in addition to eight plates. The labors of two and a half years in the radiography of projectiles in the body are digested. The old type of tubes seems to have been used throughout, gasless apparatus being alluded to but once as a subject for the future of radiography. The absence of a complete synopsis or analytical index is a drawback to the student. The volume comprises three sections, devoted respectively to the physics of *x*-rays, location of projectiles and extraction of the same. Among the brief conclusions of the authors we note that projectiles are often located by chance, that indications for extracting slumbering projectiles are still in doubt, that radiography in association with operation renders much service, that the "simplest" technique may involve operating blindly, and also dangerous exposure of the hands and that intermittent control is preferable.

CASE HISTORIES IN OBSTETRICS. By ROBERT L. DE NORMANDIE, A.B., M.D., F.A.C.S., Assistant in Obstetrics, Harvard Medical School. Price, $4.00. Boston: W. M. Leonard, 1917.

THIS, the second edition of Case Histories in Obstetrics by Dr. De Normandie, contains within its 497 pages a wealth of very valuable information arranged in a very convenient and accessible form. The general field is well covered, as are particular problems. Its information is in a form which makes it particularly well adapted to the needs of the advanced student and especially the practitioner who is practicing obstetrics without the advantages of an active hospital experience in this branch.

For the man conversant with the bedside practice either in hospitals or in one of our large outdoor obstetrical departments the case records are full of meaning, but it would seem that the selection of the very limited number of very typical cases, however enlightening and instructive, leaves much to be filled in from the experience of the reader. It is in this respect that the volume may fall short of its full opportunity in the case of the student and of the occasional practitioner. Particularly is this to be regretted in the discussion of accidental hemorrhage, a field in which almost without exception the textbooks and reference books are deficient. The suggestive cases in mastitis fall under the same criticism. They are too few in number and the emphasis is not so laid as to impress the reader with the author's very wise conservatism in the treatment of the lactating breast.

The work is to be commended for the quality of its teaching, which is of a very high standard and represents a very advanced position in rational obstetric practice.

A COMPEND OF HUMAN PHYSIOLOGY. Especially adapted for the use of medical students. By ALBERT P. BRUBAKER, A.M., M.D., author of "a Textbook of Physiology"; Professor of Physiology and Medical Jurisprudence in the Jefferson Medical College; formerly Professor of Physiology in the Pennsylvania College of Dental Surgery; formerly Lecturer on Anatomy and Physiology in the Drexel Institute of Art, Science and Industry; Fellow of the College of Physicians of Philadelphia. Fourteenth edition. Price, cloth, $1.25 net. Philadelphia: P. Blakiston's Son & Company, 1917.

WHEN a compend of physiology reaches its fourteenth edition the dignity attained through long years of service attests to the value of the work. Has there ever existed a medical student who has not used this little book of Dr. Brubaker's as a short cut through the intricacies of the details of the recommended physiologies of the curriculum? The text has followed closely on the heels of each advancement or change in medical outlook and conclusions affecting human physiology—a task of no mean proportions on the part of the author. Much former material not essentially necessary to the value of the text has been replaced by new facts in proper relation to the whole revised edition. Thus the internal secretions cover nine pages, which, in a compend of about 250 pages, and small pages too, shows the increasing importance of the newer physiology. Dr. Brubaker is to be both congratulated on the continued success of his work and thanked for the labor of many hours of detailed work, necessitated by this special type of book.

POVERTY AND ITS VICIOUS CIRCLES. By JAMIESON B. HURRY, M.A., M.D., Author of "Vicious Circles in Disease." Price, $2.00 net. London: J. & A. Churchill, 1917.

AN interesting viewpoint of this subject is offered in that poverty is made the basis of the circle and contributory conditions complete the ring. These circles are many, but the contributing causes or the resultant effects are not new, nor are they dealt with from a new angle. The author offers three channels for ultimate relief and improvement of poverty and elevation of the poor, namely, legislation, voluntary organization, and individual effort. As a reference book for social workers, church guilds, philanthropic organizations and various other charitable societies it has a decided field of usefulness.

LABORATORY TECHNIQUE. The Methods Employed at St. Luke's Hospital, New York. By Drs. F. C. WOOD, KARL M. VOGEL and L. W. FAMULENER. Price, 75 cents. New York: James T. Dougherty, 1917.

SOME of the most valuable manuals for laboratory work are those which are originally prepared as typewritten instruction for those working in the laboratory. Such is the book which has come from St. Luke's Hospital. It will probably find large use in the smaller hospitals and with private practitioners. The methods are simply and clearly given, with sufficient detail, and many points as to nicety of work are given. In his foreword Dr. Wood notes the importance of standard methods in the hospital, in order that the hospital records may be of value to the attending physicians. An even greater importance lies in the value of the records for comparative study. The book will be widely welcomed.

HANDBOOK OF SUGGESTIVE THERAPEUTICS, APPLIED HYPNOTISM, PSYCHIC SCIENCE. A Manual of Practical Psychotherapy, Designed Especially for the Practitioner of Medicine, Surgery, and Dentistry. By HENRY S. MUNRO, M.D., Omaha, Neb. Fourth Edition, Revised and Enlarged. Price, $5.00. St. Louis: C. V. Mosby Company, 1917.

THE aim of this work is to present the practical as well as the scientific side of psychotherapy, and appears from the fact that it has gone through three editions in a comparatively short space of time to have succeeded very well in the accomplishment of the intention. Two new chapters have been added, one on Suggestion in Dentistry and the other chapter dealing with the human libido has been named "The Tie That Binds and the Urge That Drives." The work is both useful and interesting.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

Stated Meeting, Held May 2, 1917.

The Challenge Which the Chronic Patient Represents to Our Profession.—Dr. JOEL E. GOLDTHWAITE of the Harvard Medical School delivered this address, in which he said that it seemed to him that chronic disease was today the greatest reproach of our profession. Furthermore, it seemed to him that chronic disease was quite as controllable as acute disease, if we only used the same methods of study that we did in acute cases. We had fallen into the habit of calling things diseases that were only groups of symptoms. If we only recognized this and tried to find the causes back of the symptoms it was amazing how some of our problems were simplified. For example, when rheumatism was treated merely by measures directed to the symptoms, such as baths, rubbing, heat, etc., we never obtained any very lasting results, but when we came to look upon the joint manifestation as simple as the smoke from the fire, and directed our treatment to the cause, we found that the joint condition cleared up in a remarkable manner. It was surprising how persons could be relieved and restored if the same principle of study was carried out in other chronic conditions. In trying to find out what was wrong with a great many of these patients they had found it necessary to study along definite lines because they saw a number of patients with somewhat similar symptoms and yet a different structure, and this had led them to go back to the anatomical field. We had been taught that we studied anatomy because it was necessary to know the structure of the human creature if we were to interpret the physiology and symptoms of disease. If we studied anatomically that type of patient called chronic we found that he had little resemblance to normal anatomy. These humans were made on absolutely different anatomical lines. There were distinct orders in humans as in the lower orders. Taking the horse we had the race horse, the carriage horse, and the Percheron; these were all built on anatomically different lines and adapted to different needs. The race horse was built on slender lines, had slim, light bones, fine, small muscles, and quick action. In the human family we found exactly the same type. They were the type of people that had been pioneers. Their skeletons weighed ten or fifteen pounds lighter than normal. Their bones were different in shape, especially the vertebrae, the lateral diameter of the vertebrae being equal to the anteroposterior, and there were sometimes six lumbar vertebrae. This made for extreme flexibility. To this type belonged the contortionists, the acrobats, the fancy dancers; their flexibility was due to anatomical structure and not to muscle training. One could never make of these the Sandow type of individual. The slender type did not appear strong, but it was frequently found that the winner in athletics was of this type. Like the race horse, he had fine, slender muscles, and power and energy. This slender type of individual not only had characteristic bones and muscles, but he had the tubular-shaped stomach, the type of stomach that when stretched became "J-shaped." That type of individual never had twenty feet of intestines, but only ten feet, and that was the reason we had difficulty in fattening him, because he had only one-half the length of intestines from which to absorb food. His colon had a free mesentery on both ascending and descending parts, the type of colon that made a sharp kink at the splenic flexure. The liver was also smaller, and there was a limited amount of retroperitoneal fat which favored mobility of the kidney, so that in this type of individuals the kidneys were easily displaced. Because of this lack of fat the adrenals lay exposed, and it was not to be wondered at that individuals of this type had sudden rise of blood pressure when one realized how easily the adrenals were irritated when certain postures were taken, nor was it surprising that there should be vasomotor disturbances from pressure on nerve ganglia. Dr. Goldthwaite stated that the normal anatomical type was much less common than it used to be; it was rarely seen in the chronic cases. He rarely saw the Percheron type in his practice. On the other hand, we had the stocky or heavy type, in which the torso was shorter, the vertebrae thicker and shorter, with a wider lateral diameter, and sometimes only four lumbar vertebrae. The skeleton was different and weighed ten or fifteen pounds more than normal. The vertebrae had broad transverse processes, and were not only heavy, but formed an articulation with the sacrum. All these peculiarities would be found in the lower animals, as in the horse and hippopotamus, animals built to carry heavy weight. Training would never convert the stocky type into the flexible type. The stocky type had coarser muscles—the kind that made the big-bellied muscles of the Sandow—though they might not have the quickness of setting of the slender type. The stocky individual had a heavier heart, which, studied with the fluoroscope, was entirely different in appearance from that of the slender type. The stocky type had also a heavier liver, and a pear-shaped stomach, attached high up. The intestines in this type were from twenty-five to thirty-nine feet in length, and that was the reason every bit of food was absorbed in its passage. The problem here was to use food that would be hurried along; for the slender type one should use bulky food. The colon in the heavy type was longer, and there was also additional length in the transverse colon; all showed the hammock-shaped colon. It was quite obvious that with such a difference in structure there would be a difference in physiology and in disease. Certain diseases were peculiar to certain types. The slender type had commonly an excess of hydrochloric acid in the stomach, and was likely to have the hyper-conditions, hyperthyroidism, etc. The stocky type had the hypo-conditions. In the heavy type the blood pressure averaged twenty points above normal; in the slender type twenty points below normal. If we got a person of the slender type with a blood pressure of 180 something was going to happen; if the stocky person had a blood pressure down to 120 it was time to look after him. Allowing for fluctuations, there were certain general averages that held good for special types. It was the slender type that had the autointoxications and infections, generally speaking, though one, of course, found some in the other type. Dr. Goldthwaite said he was not quite sure, but thought that the stocky type was more likely to have gland and bone tuberculosis, and possibly bovine; the slender type was more likely to have tuberculosis of the inherited type, and was more commonly tuberculous than the stocky type. The slender type was the most sensitively organized nervously, and perhaps the one the neurologist saw oftener than those of the stocky type, though one sometimes saw these nervous conditions in the latter type. The slender type was the one that also contributed largely to the population of the hospitals for the insane. The stocky type showed chiefly the joint diseases, osteitis, arthritis deformans, gouty conditions, etc., the conditions that had their origin in chemical disturbances. They oftener had gallstones, whereas the slender type would have cholecystitis, the result of thickened bile. In studying the patients in a hospital one would find that they classified themselves almost at once into these two classes. If we were to expect anything like a normal physiology we must see that these types used themselves correctly. The slender among the young, unless guided in childhood, formed bad postural habits and incorrect habits of breathing. If the individual stood relaxed, the ribs were lower down, and the diaphragm was lower down, and it could not contract; instead of being dome-shaped, it might even be concave downward, and as a result one had only thoracic breathing. If there was not the constant rise and fall of the diaphragm the return circulation was interfered with. Individuals with these faulty habits of posture and viscera so displaced that food could not pass through the alimentary tract normally might have indigestion from the simplest kinds of food. The problem here was a mechanical one. With the diaphragm forming a concavity downward all the viscera were displaced and the esophageal opening into the stomach narrowed. As all organs were more mobile in the slender type they more easily drooped and fell out of place. The speaker

described the manner in which the diaphragm was suspended either side of the cervical spine, and emphasized the importance of studying the way in which the diaphragm worked, as in that way much could be learned as to the position of the abdominal organs. The stocky individual was the one that commonly had difficulty on the chemical side; he had the greatest difficulty in handling large amounts of protein, and he was the one who usually ate large amounts of food, and particularly protein foods. He really required less food, as the fat did not have to be replaced. In feeding these stocky individuals one should study the chemical output and modify the food combinations until one obtained the correct chemical output. The slender individual commonly had hyperacidity, and his chief difficulty was not in the food, but in the way he handled it. It had been shown that certain individuals showed albumin or sugar in the urine as the result of mechanical interference due to sitting or standing in certain positions. Dr. Goldthwaite cited an instance of a patient showing considerable amount of albumin, there being much more albumin in the day specimen of urine than in the night specimen. Treatment directed toward the correction of the faulty posture and restoration of the viscera to their normal position had caused practically a disappearance of the albumin from the urine. The stocky adults were the ones who oftener had sugar in their urine and the slender children were the ones who oftener had sugar. There were a great many other chronic conditions due to perfectly tangible elements of strain. Many people were cripples by paralysis of progressive muscular atrophy which used to be considered a perfectly hopeless condition. Work on these patients showed an almost complete absence of blood sugar, and by doing what could be done to improve the abdominal condition remarkable results had been obtained. In many of these cases if one got rid of impressions gained from textbooks and simply stripped the patient and studied him the cause of the trouble might be ascertained. When a patient came complaining of pain, to simply say "neuritis" and write a prescription, that was not worthy of us. We should strip the patient, examine him, and go to work to fix him up. It should be remembered that in many of these conditions there was more than one factor at work. There was, for example, something more to do than to merely remove gallstones; the operation must be followed by exercises that would put the liver in a healthy condition so that it could do its work. In people in whom the diaphragm drooped the organs would all be constricted, and this type of symptoms might be explained if they were thought out in chemical terms. He had seen an instance of cardiospasm with severe vomiting which had persisted for a long time in a neurasthenic individual relieved by postural treatment, and by lying on the abdomen and supporting herself on her elbows while eating. In the postural treatment it was important that the patient lie flat on his back without pillows, in order to pull the diaphragm up into its normal position. Lying with the face downward, and the thorax supported on the elbows expanded the ribs forward and the diaphragm rose. One might support the hips on the bed and the chest and head on a stool, though it was not usually necessary to go to that extreme. Dr. Goldthwaite also spoke of the possibility of arresting a lateral scoliosis by hyperextension of the trunk and legs, thus flattening the lumbar and cervical spines, and of the postural treatment of autointoxication, and particularly emphasized the point that one should always think of the patient with hope, no matter how bad he might appear to be. Dr. Goldthwaite then exhibited charts illustrating the two types of chest deformities, (1) the flat chest, in which the lateral diameter was normal, and the anteroposterior much restricted, and (2) that type in which the ribs dropped at the side and the lateral diameter was narrowed and the anteroposterior diameter increased. The flat-chested individual was the one most likely to have tuberculosis. The stocky individual supported his weight at the dorsolumbar joint; in the slender one who was given to "droopy" postures, the strain came at the sacroiliac joint; this would explain why the latter type suffered pain at menstrual periods. At present 60 per cent. of the people were of the slender type, while fifty years ago only 20 per cent. were of that type. This type was rapidly increasing. This showed the importance of physical education in our schools. New York State was fortunate in having a compulsory physical education law. A large percentage of the students of Harvard and Smith colleges were of the slender type; this was not the fault of the colleges, but of the preparatory schools. Many of the young women were of academic mind, but of kindergarten age in body. Smith College had now taken the stand that no girl should be graduated until she knew how to use her body correctly. We should see that every child was given the chance to learn this. We should see that the people and the legislators supported the laws that we had in effect. When a patient consulted us we should think of that individual not as having something wrong with one organ, but as having many parts, and should find out which of those parts was causing the trouble at that time.

Dr. I. A. Lehman asked Dr. Goldthwaite what he considered the ideal medical school inspection system. The important thing seemed to be to find out to which type the child belonged. To get tracings such as Dr. Goldthwaite had shown it might be better to have the family physician make them, as it would not be practical in the public schools at present.

Dr. Goldthwaite said the people would have to be educated and shown that the best way to give these children the proper physical training was to get a picture. These pictures were the best records to show parents. It would be a good plan to get teachers interested.

SECTION ON MEDICINE.

Stated Meeting, Held January 16, 1917.

Dr. Harlow Brooks in the Chair.

Present Status of Fractional Estimations of Stomach Contents.—Drs. Burrill B. Crohn and Joseph Reiss made this presentation, the studies having been carried out under the George Blumenthal, Jr., Fellowship in Pathology of Mount Sinai Hospital. Dr. Burrill reviewed historically the advances in our knowledge and the present status of our knowledge of the chemism of the stomach in health and disease. He stated that in their studies they had attempted to apply the method of fractional estimation of gastric contents to persons suffering with abdominal symptoms and to ascertain to what extent and in what degree pathological processes and abnormal stimuli altered the cycle of digestion, the emptying time of the stomach, the factor of duodenal regurgitation, etc. The studies were based on over 200 curves taken from patients in the wards and dispensary of Mount Sinai Hospital, and represented all phases and varieties of abdominal disease. In a large percentage of the cases, the clinical diagnosis was confirmed by operation. Throughout the attempt had been made conscientiously to consider only such cases in which the symptoms had been clear cut and definitely indicative of pathological conditions. The technique employed had been to make the patient swallow the Rehfuss tube at 8 A. M., all food or drink having been proscribed since the evening meal of the previous day. When the question of pyloric obstruction arose, the patient ate on the previous night at 10 o'clock thirty raisins with the skins and seeds. The swallowing of the tube was an easy matter. Retching was avoided to the greatest possible degree. The stomach was aspirated in several positions until no further material was obtainable. The fasting contents were usually clear, watery, or slightly turbid in appearance. In about one-quarter of the cases bile was present in amounts varying from a tinge to a heavy golden yellow. Except in cases in which gastroenterostomy had been performed (in these bile was present constantly and in large amounts) there appeared to be no definite clinical significance to the appearance of bile in the fasting contents. When it was present it denoted a patent pylorus. The amount withdrawn from the fasting stomach varied from nothing to 140 c.c., though it rarely happened that nothing was withdrawn. In this series the amounts recovered were as follows: In gas-

tric neuroses, 2 to 60 c.c., averaging 31 c.c.; gastric or duodenal ulcer, 20 to 140 c.c., averaging 54 c.c.; chronic appendicitis, average 31 c.c.; acidity or achilia cases were either empty or showed at a maximum 10 to 25 c.c.; in functional hypersecretion, 50 to 70 c.c. The writers were unable at any time to duplicate the large amount found by Rehfuss and his coworkers in normal males, or of Fowler and Zentmire in normal or approximately normal females. The acidity of the fasting residue varied considerably, but followed in general the acid titration of the digesting meal. The acid titer was never above that of the test breakfast; usually it was lower than its maximum; in cases of hyperacidity materially lower. In those cases which approximated the normal curve the content was usually near the same figure as at the end of the test meal. This should be designated as the minimal acidity of the stomach. In cases with normal or slightly acid curve the fasting titration showed free acid of 32 to 52 per cent; total acid of 44 to 68 per cent. In subacidity cases, free acid was absent and total acidity diminished to 20 per cent. Mucus in small amounts was present in all cases, and was usually markedly increased in cases of chronic gastritis, marked subacidity, and carcinoma. Food particles, recovered by this method, had the same significance as when found by any other method, namely, were highly suggestive of pyloric obstruction. When food residue occurred a higher acidity titration was the rule. Blood had been noted only in cases of carcinoma. A heavy oatmeal gruel was utilized as the test meal. The gruel was made by adding two tablespoonfuls of oatmeal to a quart of water and boiling it down until it was reduced to a pint in volume. It was then filtered and a pinch of salt added. Lavage was practiced before giving the test meal. Every ten or fifteen minutes after the administration of the test meal, ten to fifteen c.c. of the stomach contents were aspirated for examination. In a group of cases numbering over 50, in which were included all cases free from organic disease, many illustrations of normal curves were noted. The pure gastric neuroses and the so-called normal cases fell into this group. Free acid appeared soon after the beginning of the test; maximum total acidity, 60 to 70 per cent., was reached at about one hour; thereafter there was a slow decline, approaching the base line though never reaching it. The stomach emptied itself usually in from two to two and one-half hours. The course varied but slightly in the hypersecretory cases, the total acidity reaching slightly high levels, 80 per cent. and over. These latter cases emptied themselves in the same time, though the fall in acidity was slower and did not approach the base line until later, if at all. The hyposecretory type was essentially the same as the isosecretory. In cases of anacidity there was a lack of free hydrochloric acid throughout, though the total acid might have risen to 20 or 30 per cent. at some time of the digestion. Ferment strengths were maintained, fasting contents were usually absent or of minimal quantity, and the stomach emptied itself within two hours. In the achylia cases, free acid was consistently absent throughout; total acid fluctuated between the extremely narrow limits of 8 to 10 or at most 14 per cent. The emptying time was shortened to one and one-half to one and three-quarters hours; ferments were absent. A distinct classification of psychical and chemical achylias they had been thus far unable to confirm. Since achylia gastrica should be regarded merely as an advanced stage of anacidity, those cases with the late rise of acidity belonged properly to the class of anacidity; rather this was better than to create a new classification of "spurious achylia" (Rehfuss). Some of the most advanced examples of achylia occurred in cases of pernicious anemia. Ferments as well as mineral acids were lacking in these instances. While it could not be said that there was a curve absolutely characteristic for ulcer yet it might be conservatively stated that ulcer cases were associated with a curve of acidity that rose rapidly and was sustained throughout the cycle of digestion, at least to within a short time of its end. It was the steady, rapid, prolonged rise, and sustained plateau of acidity that was seen in the ulcer cases. The fall, if it occurred at all, took place just before the final emptying of the stomach. A delayed motility was frequently a factor, and indicated pyloric involvement, either functional or organic. The regurgitation of bile was most commonly absent or took place only at the very last phase of the digestion. The presence of mucus was not associated with ulcer, though occasionally it was seen in large amounts in the fasting contents at the termination of the period of observation. In spite of what might have been expected blood was absent throughout. In all of these cases the highest acidity took place not one hour after eating, but 1¾ to 2½ or 3 hours after giving the test breakfast. No case of subacidity had been noted in this series of ulcer curves. A mild hypersecretion was occasionally noted. Chemical analysis of the postdigestive in these ulcer cases showed it to correspond closely to the analysis of pure gastric juice as found in the standard text books. Cases of pyloric stenosis showed moderate acidity at the outset. Up to the present time the authors had found no possible means to differentiate the acidity curves in cholelithiasis and chronic appendicitis from those of ulcer. The postgastroenterostomy cases showed normal or subnormal acidity curves characterized by a drop in acidity at the end of the first hour. The curves in cases of carcinoma ventriculi were those of marked subacidity, occasionally those of anacidity. The almost flat curve of achylia was rarely seen in these cases. The gastric ferments were retained in all the cases and blood which was practically never seen in other conditions was very common. Chronic parenchymatous nephritis, the convalescent stage of acute intercurrent infections, and syphilis of the stomach gave a curve of subacidity without novel characteristics. One who expected to find in the curves of the fractional digestion a new and infallible diagnostic criteria would be disappointed. For the demonstration of digestive hypersecretion the method was unequalled. Its great value lay in the fact that it offered knowledge regarding the physiology of the entire cycle of digestion. Through it one could gain information on the following points: (1) Fasting contents—amount, presence of food residue, regurgitated bile, mucus and blood. (2) Type of secretory activity. (3) Duration of secretory activity, whether ceasing with the exit of food or maintained as a hypersecretion thereafter. (4) Time of emptying the stomach, that was, its motility. The field of usefulness of this method for the study of defects of medication, dietary, therapy, psychical influences, operative procedures, etc., was unlimited.

Roentgen Diagnosis of Early Gastric Cancer. — Dr. WILLIAM H. STEWART made this contribution. He stated that it was not his desire to excite any rivalry to the different methods of the early diagnosis of gastric cancer. Realizing the difficulties that must be overcome in order to accomplish this ideal, he earnestly advocated combining all "methods" before arriving at a conclusion. The fact was that it was not always possible to make an early diagnosis of carcinoma of the stomach as many cases did not present themselves until the process was well advanced. Those who sought advice early presented fairly typical *x*-ray findings. It was recognized that gastric cancer appeared in three forms, a true tumor growth of the stomach wall, a scirrhous or infiltrative type, and an ulcerative form. The difficulty of diagnosing the first was not difficult. The *x*-ray findings were characterized by a circular or irregular defect in the stomach outline. If located at the pylorus, the defect had a "punched out" appearance, while if located on the anterior or posterior wall, it showed itself as a central defect in the shadow of the stomach. In the scirrhous form there was a stiffening and thickening of the stomach wall with contraction and diminution in size and there was a partial or complete absence of the peristaltic waves through the involved area. Under the fluoroscope, the contraction passing toward the pylorus from the fundus coming upon this thickened segment became greatly diminished or disappeared entirely to again appear beyond this area, if there was normal stomach wall between the diseased portion and the pylorus. It was in the third or ulcerative form that the greatest difficulties presented themselves. Since it must be conceded that the presence of carcinomatous tissue in an early ulcer could only be ascertained by the microscope, they had a large number of cases between a typical carcinoma and an unquestionable benign ulcer in which

the diagnosis of malignancy was doubtful. Before obstruction or palpable tumor appeared, many of these cases, showed roentgenographically as small annular growths at the pylorus or as ulceration on the lesser curvature of unusual size and were undoubtedly malignant; still it would be manifestly unjust for the roentgenologist to say that carcinoma was present when the problem could not be solved until the pathologist had made a microscopical examination of a section taken from the proper portion of the ulcer. What the roentgenologist could do was to report that the case was probably malignant and must be considered so until proved otherwise. If this rule were followed, the case would soon reach the surgeon's hands where it belonged. A recent canvas on the importance of the *x*-ray examination in early cancer of the stomach showed that a number of observers who had a wide experience in making roentgenological examinations in cases of suspected gastric cancer assigned to this method of examination a great value, some even regarding the negative diagnosis as of decided value, these findings being based on lack of defects in the stomach wall, absence of interference with peristalsis, and no tendency to obstruction. The greatest difficulty experienced in the *x*-ray diagnosis of early gastric cancer was the elimination of the spastic element. Some small ulcers at or near the pylorus would give a typical appearance of an annular growth. Persistency of such a defect, both fluoroscopically and roentgenographically, with a confirmatory examination after the administration of an antispasmodic for a few days, would usually clear up the case. The roentgenologist should be allowed to hold his patient under observation for a sufficient period of time to thoroughly confirm his diagnosis. That syphilis of the stomach could readily be mistaken for an early malignancy there could be no question. It was, therefore, advisable to have a Wassermann test made on all suspected cases before surgery was resorted to.

Dr. L. T. Le Wald amplified and emphasized the points that Dr. Stewart had brought out. He showed slides of syphilitic stomachs that had come under his observation. One of these was a small rapidly emptying stomach. The diagnosis in this instance was made on the youth of the patient and the four plus Wassermann. She was put on active antisyphilitic treatment and the pyloric condition came under control. Another plate showed a very similar condition but the stomach wall was more involved and there was a dilatation of the esophagus. This patient was operated on because there was such a degree of stenosis. A gastroenterostomy was performed and this, together with antisyphilitic treatment, effected a cure. A third case was that of a boy, 14 years of age, who complained of indigestion. It was thought that he might possibly have a complicating appendicitis. As he showed a four plus Wassermann he was put on the iodides and now, four years later, he was quite well and still had his appendix in him. The slides showed the condition of other cases, before treatment and two years after; the stomach had regained some of its contour. Another plate showed a persistent deformity of the greater curvature near the pylorus and in this instance there was also a four plus Wassermann. This patient had 24-hour gastric retention and gastroenterostomy was performed. Dr. Le Wald also exhibited slides showing the typical picture of annular carcinoma. He stated that he had had five such cases in which the *x*-ray examination had furnished confirmatory evidence of the condition; resection was accomplished in these cases. All five patients were alive three to five years after operation.

Dr. John Douglas said he wished to confirm the contention of Dr. Stewart as to the value of the *x*-ray examination both in the diagnosis and operability of carcinoma of the stomach. In this connection there were two points worthy of discussion. The first was that these patients did not always present themselves for early diagnosis to the surgeon, the physician, or the roentgenologist. This statement might be confirmed by any number of cases, particularly by one on which he had recently done a resection for a large carcinoma in the lesser curvature, which became adherent to the liver and had even involved the liver without producing any definite symptoms indicative of carcinoma. This man had absolutely no stomach symptoms up to three months before he came under observation. He gave no history of pain in the stomach or abdomen at any time; his only symptoms were occasional discomfort and occasional vomiting and loss of flesh and strength. As Mayo has said, carcinoma of the stomach *per se* caused no symptoms. Secondary symptoms resulted from pyloric stenosis ulceration, etc., caused the symptoms, hence we must often rely upon other means than clinical symptoms in making an early diagnosis of carcinoma of the stomach. Such extreme statements as those of Friedenwald that after operation for carcinoma of the stomach patients alive for any considerable length of time should not be allowed to gain credence for if both physician and patient felt that operation offered no hope there would be no use in making an early diagnosis. Dr. Douglas said his experience included 10 cases of carcinoma of the stomach on which he had performed resections. Of these 10 cases 3 were still alive at the end of four years or more and one six months after operation. Of the six deaths that had occurred, three were not directly due to the carcinoma, one being due to postoperative embolic gangrene of the leg, one to heat stroke following the operation, and one to the operation. Three had lived for a period of 6 to 18 months after operation. Four were alive and well, and such a result was certainly more encouraging than the attitude of pessimism that was current. One patient had come under his observation who had had a palpable tumor of which she was aware for over a year and whose condition might have been considered inoperable according to the dictum that when a tumor became palpable operation offered no hope of a cure, yet that patient had been operated upon and was alive at the end of almost five years.

Dr. Julius W. Weinstein said he would like to present the *x*-ray plates taken from a case which was rather interesting, because it showed that the examination of the stomach contents was no mean factor in making a diagnosis of carcinoma of the stomach. The patient was the father of a physician who had suffered from stomach trouble for many years. During the past five years, however, he had been in perfect health. He came under the speaker's observation November 2, 1916, with a history of five weeks' duration. He suffered with discomfort after eating, lost his appetite, and was very weak. His bowels became constipated. He vomited his food. There were no other symptoms. On physical examination all the organs were negative. There was some rigidity in the region of the stomach. An *x*-ray examination of the stomach, both fluoroscopic and roentgenographic, was negative. The motility of the stomach was good. The small intestines and colon were normal under the *x*-ray. A test meal examination showed, however, that the stomach contents were poorly digested. Microscopical examination showed some epithelial cells, some Boas-Oppler bacilli, and a few other microorganisms. There was no free hydrochloric acid. The total acidity was 14; combined acidity 0. Lactic acid was presented. In view of the negative *x*-ray examination the speaker thought the case might have been one of an exacerbation of achylia gastrica, since the patient had a long past history of stomach trouble. A strong suspicion of carcinoma, however, was expressed. Seeing that the patient's condition was not improving, about ten days later another test meal was extracted which showed that the contents emitted a fecal odor. Microscopically the stomach contents were full of Boas-Oppler bacilli. A positive diagnosis of infiltrating type of carcinoma of the stomach was made. The patient's son wanted to consult other men in view of the hopeless prognosis and he put the patient under the care of Dr. Basch. The latter made radiographs of the patient about one week later and by this time the radiographs showed a destructive process of the stomach due to the invasion of the carcinoma. The patient died January 7, 1917, as a result of hemorrhage of the stomach. This case was one of a fulminating type of cancer of the stomach. Dr. Weinstein said that while he knew and appreciated the brilliant services of the *x*-ray in the diagnosis of cancer of the stomach this case proved that it was not infallible and that other aids to diagnosis must not be neglected.

Dr. Seymour Basch said that the plates which Dr. Weinstein showed spoke for themselves. One would be quite unable from these plates to say that carcinoma was present. The patient had an area of tenderness at the xyphoid-costal angle and clinically presented the typical appearance of carcinoma, the cachexia, etc. There was stagnation of the stomach contents as much as 60 c.c. having been withdrawn at one time. There was one point which Dr. Stewart failed to bring out and that was the possibility of mistaking a syphilitic condition for one of early malignancy. In these cases the Wassermann test was not enough to clinch the diagnosis; a positive reaction might indeed be misleading as it would tend to verify the syphilitic condition and lead one to throw out a carcinoma. Here only the ultimate therapeutic test or laboratory study of the excised tissue could often decide the diagnosis of early carcinoma. One point not brought out should be mentioned and that was the finding of a thinning of the center of the opaque stomach shadow in carcinoma of the body of the stomach.

Dr. William H. Stewart said he had tried to be perfectly fair in his statement that the roentgenological examination must be combined with other methods in reaching an early diagnosis of gastric cancer. Medical men assumed rather a peculiar attitude toward the *x*-ray. Most of them acknowledged the value of the roentgenological examination yet whenever the opportunity presented itself they were sure to make unfavorable criticism and to question its value. Dr. Weinstein cited a case which gave a history of cancer and made the statement that the *x*-ray examination showed no indications of the presence of a defect, but he did not say who made the examination. The speaker's paper had emphasized the fact that the roentgenological examination of a case of suspected malignancy should be entrusted to one well trained in roentgenology; this case should not have been presented as antagonistic to the value of the *x*-ray examination. It was gratifying to hear Dr. Douglas speak as he did of the operability of gastric carcinoma; the impression had gained too much credence that all operations for advanced gastric carcinoma were hopeless. Dr. Erdmann and Dr. Bainbridge had each recently reported a number of cases in which late operations which might have been considered as offering little prospect of success had resulted in apparent cures. Dr. Stewart said he wished once more to emphasize the importance of excluding syphilis where one found a persistent defect before having recourse to surgery.

The Diagnosis of Duodenal Ulcer. — Dr. Anthony Bassler spoke on this phase of the subject presenting the clinical side without going into the other methods of diagnosis or dwelling on the points that were well known. He said that all present knew the classical syndrome of Moynihan of pain coming on between two and four hours after a meal, relieved by the administration of alkalies, but not belladonna or atropin, or by the taking of foods which closed the pyloris for the time being. These patients had a history of remission of symptoms, were generally somewhat emaciated, and were usually men. He agreed perfectly with what Moynihan had stated in this connection, although he did not agree with the close of his description—namely, that the presence of these symptoms justified an operation, because there were instances of duodenal ulcer cases that got well on medical treatment. Although the discrimination necessary to pick out those cases that would respond to medical treatment was a very fine one, it still was practical to a considerable extent. The type of cases with the clinical syndrome was so characteristic that his own secretary in taking the history had on three or four occasions made the diagnosis, and she always was right. The type of more interest, however, was the one without the characteristic symptoms. If one went carefully into the history, while the element of pain was absent, or so slight that it could not be designated as "pain" there were certain points that were suggestive in a mild way. Such cases sometimes presented on fractional extraction, or extraction of the Ewald test meal one and one-half or two hours after ingestion, the presence of blood. Ofttimes this was difficult to observe by the microscope in the mess of carbohydrate substance, but could be found present on chemical test. In these cases the *x*-ray as a means of diagnosis was very valuable. Such cases commonly presented the colloquial symptoms of indigestion—namely, post-meal distress, gas, pressure, eructations, etc. There were probably more instances of duodenal ulcer unrecognized during life and healed of themselves than were present in medical ways. Careful studies of the duodenum at post mortem show that healed lesions of the duodenum were common. What was interesting in this connection was that when a duodenal lesion healed it healed well, and the evidences of their having been a lesion at some time often could not be observed excepting by careful microscopic study of the sections. It was probable that a proportion of these cases presented at some time during life the colloquial symptoms of "indigestion" and with the healing of the lesion a cessation of these. The natural inference here would be that there had been no lesion of the duodenum but years afterward it would show on careful examination of the tissue. He felt further that the theatrical aspect of the perforation cases justified no extension of remarks on his part, because his experience has been that practically all of them were being suspected or diagnosed when seen. In this connection he doubted that it was important to differentiate as to whether the rent was in the duodenum, gall bladder, or stomach. The indications for treatment were the same in all—namely, surgery, and all these tissues were in such close proximity that they could be examined in a few seconds. Occasionally, however, these patients gave a previous chronic gall bladder history, a history of duodenal ulcer, or that of gastric ulcer, and in such cases it is sometimes possible to state with reasonable accuracy which tissue had perforated. In his experience the perforations had been mostly in the florid types of ulcers where there was no organization of tissue suggesting a chronic lesion, usually a soft irregular ulcer formation of the mucous membrane and then more or less of an irregular tear through the peritoneum. They apparently are more of a necrosis ulcer type and had been most often seen in alcoholics. Dr. Bassler's experience in the differential diagnosis of duodenal ulcer comprised mostly four conditions which it could simulate. The first was hypersecretion. In these conditions, and he did not take the time to classify them, one had relief from the symptoms by the taking of alkalies, but here belladonna was useful. Ofttimes there was relief from the symptoms by the taking of foods. Of course, the element of pain was absent, although there might be suggestions of a remissive type in the running course of a case. What were valuable here were the observations and examination of test meals, the absence of blood, and a negative *x*-ray. Also the benefits from logical treatments were definite, and not observed in the average duodenal ulcer case. The next were atonies. He used to think that atony of the stomach was a common condition, but he has come to change his mind. One could not depend upon a marked splash as being significant. Many stomachs (gastroptosis) were so low in the abdomen that they did not get the protection of the costal arch, and in agitating abdomens of such cases a splash was common. His studies of atonies suggested that it was a rather uncommon condition so far as demonstration by test meal and *x*-ray examinations had proved. However, such cases did exist, in which there was no obstruction of the pyloris, and it was sometimes observed that such an one would give symptoms moderately suggesting a duodenal ulcer. Here the test meal extracted denoted a moderate degree of delay and the *x*-ray a negative cap. Here, like in hypersecretion, the results of treatment were good. The next was appendicitis, leaving out of consideration acute appendicitis with its characteristic symptoms of pain and spasm, fever, increased pulse rate and leucocytosis, there were cases of chronic appendicitis running frequent attacks of low forms of subacute inflammation which might simulate duodenal ulcers. Naturally the physical examination would suggest the mischief being in the lower right side of the abdomen, and here he suggested that not enough detailed attention was being paid to the diagnosis of chronic appendicular conditions. Operations were engaged in, appendices were removed, and people were not relieved of their digestive trouble. If men would take the trouble to percuss the cecum, make their point pressures at

the base of the appendix, carefully examine appendices by the *x*-ray, marking pressures along their course when possible of visualization, they would not go so far wrong in diagnosis. In his experience there were appendices that should have come out wherein surgeons advised against it, but more often there were appendices which should not come out so far as relief of symptoms was concerned, which they insisted upon removing. There were reflexes from the region of the appendix and other things to make it possible to differentiate the condition from duodenal ulcer. Still, there was occasionally a case of this sort which presented considerable difficulty. The last conditions to differentiate from ulcer were the gall bladder pathologies, and here the greatest difficulty was met with. One sometimes meets with small quantities of blood in the test meals and stools, and it is not unusual to have adhesions springing from the gall bladder and involving the duodenum giving irregular shadows suggestive of ulcers. One point he drew attention to was that these irregularities were usually on the inferior surface of the cap whereas duodenal ulcer lesions were on the superior. What was confusing in these cases was that not uncommonly the patient gave a history of distress coming on about two or more hours after meals. He thought this was due to the gall bladder functioning actively, and, being in a diseased condition, the distress was a cry from that viscus. We knew that the gall bladder was a reservoir intended for the purpose of having a considerable amount of bile ready for active digestion, and it was being poured into the duodenum about two hours after the meal. *X*-rays might show a visible gall bladder—which was always pathological—or stones. What was still more confusing was the occasional case in which both a gall bladder pathology and duodenal ulcer existed at the same time. But these cases were usually actually ill, the symptoms of disturbance being marked, and that was helpful in differentiating. What was also of help in differentiating gall bladder pathology cases from duodenal ulcer was that there might be no relief by taking alkalies and foods—the condition being extragastric. Of course, in these cases there was a tenderness in the median fissure of the liver, this not being present below in the abdomen. In closing Dr. Bassler said that altogether he thought that the diagnosis of duodenal ulcer was relatively easy. The history was of the most value, the *x*-ray second, the laboratory third, and the physical examination not worth much.

The Treatment of Duodenal Ulcer from the Medical Standpoint.—Dr. W. A. BASTEDO presented this phase of the subject. He stated that the treatment of duodenal ulcer differed markedly according to whether or not the ulcer was in the phase of severe hemorrhage, and, if not, whether or not one had a surgical condition. At the time of severe hemorrhage, the immediate treatment was: (1) To secure physical and mental quiet, by having the patient lie flat without a pillow, and with an ice bag over the epigastrium, and by the administration of morphine, which allayed restlessness, diminished the chances of vomiting, took the tone from the general stomach muscles, induced closure of the pylorus, and thus assisted in keeping the duodenal ulcer region free for the time being from gastric contents. (2) To give nothing by mouth, not even a teaspoonful of water or cracked ice. (3) To allay thirst by the rectal administration of a pint or two of warm saline solution. If the patient was exsanguinated, 1000 or 1500 c.c. of normal saline by hypodermoclysis or venous infusion might be administered, or best of all, if it was feasible, a transfusion might be done. If the hemorrhage appeared to be continuous one might inject subcutaneously, every six hours for three doses, 20 to 30 c.c. of human or rabbit serum, or intravenously 20 c.c. of a freshly prepared 10 per cent. solution of normal saline coagulen or coagulose. It took the serum six to twelve hours to affect hemorrhage. One might employ subcutaneously or intramuscularly, but not intravenously, a like amount of a 10 per cent. saline solution of thromboplastin. The calcium salts were probably of little if any value. As a rule surgery was not indicated at the time of a hemorrhage from a duodenal ulcer, because mostly the hemorrhage ceased spontaneously or as a result of the measures taken. The subsequent treatment was to continue the quiet of the patient by keeping him in bed; allowing nothing by mouth for three days, and allaying thirst by rectal salines, one-half to one pint every four to eight hours, or by the Murphy drip; giving 2½ to 7½ ounces per hour; cleanse the bowel by daily soapsuds enema; giving a nutrient enema two or three times in twenty-four hours; keeping the mouth clean as with peroxide of hydrogen or simple mouth washes, and after the end of three days treating the same as for ulcer when there was no hemorrhage. As to the treatment of ulcer at the time when there was no severe hemorrhage, if the case was definitely surgical there was no use wasting time on the medical treatment. Dr. Bastedo stated that he considered the treatment surgical if there was acute perforation; if there was chronic perforation, as demonstrated by the Roentgen rays; if there were adhesions as demonstrated by the Roentgen rays; if there was pyloric obstruction; if there was suspicion of carcinomatous change; if, in spite of proper medical treatment, the ulcer was the site of repeated copious hemorrhages, or persistent hemorrhage in small amount, and if there was constant pain or nausea or interference with nutrition. If the ulcer was not surgical, the relief of symptoms by medical treatment was, as a rule, quite prompt. The failure of relief of symptoms by medical treatment suggested that the condition was surgical. As an aid in determining whether a pyloric stenosis was inflammatory or cicatricial and not edematous or spasmodic the patient might be put to bed on the ordinary ulcer diet and medication and in addition a daily lavage, best late in the afternoon might be given. In some of the retention cases, the milk diet resulted in such marked milk sourness as to render the use of milk impossible. In this event the diet might consist of strained cereal with butter, potato, macaroni, wetted bread or toast, soft egg, and perhaps shredded chicken or scraped cooked beef. If these measures did not overcome the retention, the treatment was surgical. The treatment of an ulcer that was nonobstructive and nonsurgical should be purely medical and should consist in rest in bed for three or four weeks, and then allowing the patient to sit up a little each day, gradually to sit up longer and to walk an increasing distance each day, always short of fatigue, until at the end of six weeks he might be up the greater part of the day but he should lie down after each feeding. The length of time before the patient could attend to his usual affairs was at least two months. During the entire time a reasonable amount of mental calm favored the cure. Dr. Bastedo said the names and diets of Lenhartz and von Leube, etc., should be forgotten. Meals should be small and frequent, every hour during the waking hours, so that they might satisfy the need and prevent the accumulation of acids. The food should be bland, nonirritant, and arranged to combat hyperacidity and hypersensitiveness of the stomach. No coarse, gritty fibrous particles should be allowed, and no spices, seasoning or saltiness; the food should not be ice cold (except Lenhartz). There was nothing better than milk, eggs and cream. If it was desirable to prevent the coagulation of milk by the rennet ferment, three grains of sodium citrate might be added to each glass. The medicinal treatment at the outset consisted of antacids, demulcents, and laxatives, that was, drugs to combat hyperacidity and hypersensitiveness with pylorospasm, and measures to avoid intestinal stasis. At the end of the second week castor oil for a thorough cleansing, or calomel, one grain, (¼ grain every one-quarter hour) followed the next morning by a saline cathartic and after that mineral oil, one-half to one ounce, two or three times a day. The mineral oil tended to decrease acidity and sensitiveness, to relax the pylorus, to soothe the ulcerated area, and to act as a laxative. It was not to be expected that a cure could be obtained unless the bowels were kept in good order. Chlorosis, but no other form of anemia, might be successfully treated by daily hypodermics of 0.5 to 1 c.c. of a 10 per cent. solution of iron and ammonium citrate. After outlining the measures to be employed in meeting special indications, such as pain, distention, vomiting, retention, and hyperacidity, he stated that in some cases in which a course of a week or two of ulcer diet was unsuccessful in abolishing the pain or other symptoms, or when the

ordinary ulcer treatment was followed soon by recurrence, a course with duodenal feeding might be successful. In duodenal ulcer without obstruction the intermittent character of the attacks made the patient seem to be cured when he was not. Freedom from pain and discomfort obtained by proper treatment did not of necessity mean a cure until time proved it to be permanent.

Dr. E. A. Aronson said that he took exception to the remark of Dr. Bassler's that it was easy to make a diagnosis of duodenal ulcer, and wished to ask the reader how many of his cases were confirmed by operation or otherwise. From a large experience in the gastroenterological service of Mt. Sinai Hospital in making a diagnosis most reliance was placed on a proper consideration of the history, physical examination, laboratory findings, and *x*-ray. The physical examination showed that it would be extremely unwise in making a conclusive diagnosis without a distinct point of tenderness; the chemical examination sometimes gave assistance and sometimes it did not. As far as the *x*-ray examination was concerned, most frequently it corroborated the presence of an ulcer. It had been their experience that even with a significant history, positive physical, chemical, and positive *x*-ray the surgeon on operation found no ulcer to be present and conversely found an ulcer where none had even been suspected. Until an absolute diagnostic sign of ulcer was discovered, just so long would patients be submitted to the surgeon whose operation always began as an exploration.

Dr. E. Libman said he agered with Dr. Aronson that the diagnosis of duodenal ulcer was often very difficult, and he was surprised to hear that anybody considered that it was always a very easy diagnosis. If the case had repeated hemorrhages, or had an *x*-ray diagnosis which pointed to complete or incomplete perforation, the diagnosis was, of course, definite. In many cases, however, the *x*-ray examination gave findings which could be found in other forms of disease in the abdominal cavity, particularly in disease of the gall bladder and appendix. Dr. Libman said that in some cases he could only make a diagnosis after he had with difficulty excluded the presence of tuberculosis of the lungs, gallstones, prostatic disease, chronic obliterating appendicitis, renal calculus, diseases of the uterus and adnexa in women (in some cases fibroids gave symptoms that were suggestive of atypical clinical pictures of gallstones or ulcer), and a peculiar form of gastric disturbance which occurred at or following the menopause or after hysterectomy, and neuorses. It was his custom, however, he said, to have *x*-ray examinations made in all the cases because even if typical findings were not present, one obtained evidence that there was organic disease in the abdomen.

Dr. Lewis Gregory Cole stated that the diagnosis, by means of serial radiography, was possible in practically every case of duodenal ulcer. Postpyloric ulcers showing an obliterated cap and pyloric or postpyloric stenosis, with either broken or failing gastric compensation, demanded surgical intervention. Postpyloric ulcers showing a deformed or obliterated cap without stenosis, but with a deep crater, and thick, turgid edges, required surgical intervention. Postpyloric ulcers showing an obliterated or deformed cap and secondary gastric involvement required surgical intervention for a removal of the induration. Postpyloric ulcers showing an obliterated or deformed cap and with compensating peristalsis were a border line group, and as large a percentage did as well on medical treatment as do those treated surgically. Postpyloric ulcers showing a simple cap deformity with or without slight stenosis and with a normal or compensating peristalsis, and without deep crater or secondary gastric involvement were more completely relieved of their symptoms by medical treatment than by surgical intervention. This last group with indication for medical treatment comprised 63 per cent. of his cases; the preceding groups with indication for surgical intervention comprised 37 per cent. A few of the cases in the medical group would exhibit symptoms so severe that surgical procedure would be necessary, but even after interference they did not show the satisfactory results that were shown in the groups where there was definite indication for surgical procedure.

Dr. Gedide A. Friedman said he would like to emphasize that the diagnosis of duodenal ulcer was occasionally difficult. He cited the case of a patient who had all the so-called classical symptoms and signs of duodenal ulcer, late pain, hunger pain, night pain, and positive tests for occult blood in the stools. The radiographic examination also favored the diagnosis of duodenal ulcer. Dr. Brill, under whose service the patient had previously been, diagnosed the case as duodenal ulcer. Dr. Friedman referred the patient to Dr. Gerster, who at operation stated that he palpated a callous ulcer in the first portion of the duodenum. Shortly after the operation, the patient died from intestinal hemorrhage. An autopsy was performed, but no duodenal ulcer was found. There was, however, an accessory pancreas from which the bleeding probably originated. This was only one illustration of many that might have the typical history of duodenal ulcer and confirmatory *x*-ray findings, and yet at operation no ulcer would be found. Great progress certainly had been made in the diagnosis of duodenal ulcer, for only as far back as fifteen years ago the diagnosis of this condition was a mere accident. Although he admitted that *x*-ray examination was a great help in the diagnosis of duodenal ulcer, yet he disputed the statement of Dr. Cole that the diagnosis could be made certain in every case of duodenal ulcer from radiographic findings.

Dr. Alexis V. Moschcowitz said that for allaying thirst, water was better than the saline that Dr. Bastedo had mentioned in his paper; the saline had a tendency to increase thirst. He was rather radical in the belief that where there was bleeding in duodenal ulcer there was a distinct indication for operation.

Dr. W. H. Stewart said there seemed to be a great discrepancy of opinion as to the ease with which the diagnosis of duodenal ulcer could be made. He had recently heard Dr. Deaver of Philadelphia read a paper in which he reported a series of 200 cases of typical duodenal ulcer, and only eight atypical cases, in all of which the diagnosis was made largely on the history. In reality the diagnosis was not easy; it required a great deal of skill. Dr. Stewart said he would like to ask Dr. Bastedo how much food he gave these cases in the beginning. He had said a small amount. How much was that? He would also like to hear him say whether he placed any dependence on hyperperistalsis as an indication of the progress that was being made in the treatment. His own experience had been that during a period of quiescence the hyperperistalsis continued. Dr. Stewart also brought out the point that duodenal ulcer might be dependent upon mechanical interference in the bowels, and if this factor was involved, one must direct attention to the entire alimentary tract before operating for duodenal ulcer.

Dr. J. W. Weinstein said there was considerable divergence of opinion as to whether the diagnosis of duodenal ulcer was easy or difficult. He considered it easy. The syndrome Dr. Bassler had mentioned made it easy. The *x*-ray gave some assistance, and it could also be diagnosed clinically. The trouble was they had been devoting all their attention to the physical examination; more care should be given to the taking of the history. There were takers and takers of history. It would be interesting to know in how many cases diagnosed as duodenal ulcer the diagnosis was sustained at operation. All surgeons agreed that in making a diagnosis the first reliance was to be placed on the history.

Dr. Patterson called attention to the alkaline treatment advocated by Sippy, who gave alkali every hour and removed the stomach contents at bedtime by means of the stomach or duodenal tube. Sippy's claims that he had never seen a case that could not be cured by his method were rather extravagant, but the treatment might be worthy of mention in connection with Dr. Bastedo's paper.

Dr. Bassler, in closing, said that the effects of alkalies in relieving distress in ulcer cases was not so much due to their neutralizing action on the gastric juice, but to their sedative action on motility. He was reminded that in 1910 when the first edition of his text book came out he took the stand that a proportion of duodenal ulcer cases were possible of cure by medical means, this being at the time when the

subject was considered definitely surgical, and he was glad to see that his experiences were being substantiated, but he did not agree with Dr. Cole that two-thirds of duodenal ulcer cases were medical. He felt that not more than one-third were, considering the condition of patients two years after treatment. Regarding the number of duodenal ulcers which he had diagnosed and treated medically, he, of course, could not be sure of a lesion. He had no records to substantiate him, but the number that had been operated upon were not a few—probably somewhere between fifty and one hundred, and up to the present time he had not missed in one. In every instance a lesion in the duodenum was present which was believed to be an ulcer, and it was on the basis of this that he claimed that the diagnosis was easy. He stated that all these cases had been examined by *x*-ray, and that this, with the history, was the reason of his success. He did not think that the importance that Dr. Aronson placed upon tenderness on pressure in duodenal ulcer cases was worthy of much significance. It was the last thing that he expected to find in any definite way and most of his operated-upon cases had no tenderness.

Dr. BASTEDO, in closing the discussion, said he had been asked about the amount of food he gave at the beginning. He started with three or four ounces, or sometimes only two ounces, of peptonized milk, being guided by the tolerance of the patient's stomach. In regard to the question as to whether he judged that a patient was cured by the stopping of the hyperperistalsis, he had not followed the patients sufficiently by the *x*-ray to say, but he thought there might be a justification for following up this line of observation. The persistence of hyperperistalis, especially if there were in addition alternating phases of open pylorus with rapid emptying and pylorospasm with temporary retention, would suggest the continued presence of the ulcer. Sippy had treated a large number of cases of ulcer, possibly more than any one else in the United States. It did not seem possible that he could have been successful with his method of treatment in a large number of cases of pyloric obstruction, though he stated that he did so believing that a large number of cases gave a condition of obstruction due to edema or inflammation or reflex spasm, which for a time resembled cicatricial pyloric obstruction. In obstruction cases he would be prone to set up a serious milk sourness with the milk and cream treatment.

THE NEW YORK PSYCHIATRICAL SOCIETY.

Stated Meeting Held January 3, 1917.

DR. L. PIERCE CLARK, PRESIDENT, IN THE CHAIR.

On the Place of the Psychiatric Clinic in Prisons.—Dr. BERNARD GLUECK, Psychiatrist to Sing Sing Prison, read this paper. The clinic was established August, 1916, and was supported by the Rockefeller Foundation. A broad program of activity had been laid out. The functions of the clinic were to be both scientific and applied, and to this end a reception service had been organized. The normal individual should be segregated from the abnormal, and the abnormal should be studied; the origin of antisocial behavior should be investigated. For reconstruction purposes a study of the aptitudes for vocational training and social adaptation was being undertaken with a view to increase individual efficiency and to develop a motive and capacity for work, instead of a continuance of antisocial tendencies after being discharged. Promising results were being obtained. Follow-up work had been instituted, and therapeutic interviews with convicts were arranged for through a daily clinic. The clinic had further facilitated the work in several of the penal administrative departments, notably by furnishing more exact data to the parole board, by assisting in the revision of the local and State plans for prison development, and by suggesting modifications in prison legislation. The speaker referred to an affiliation with a university which promised reciprocal values to both institutions. The great ameliorating effect of the Mutual Welfare League upon prison conditions and prisoners was dwelt upon and its extended value beyond the prison days was remarked. Considerable case material and graphic charts were submitted.

Dr. THOMAS SALMON spoke of the great theoretical and practical value of this work, and the growing interest near and remote municipalities and States were taking in the Sing Sing object lesson. In New York City eleven psychiatrists were now employed to study and advise in matters pertaining to criminality and the broader disorders of conduct and delinquency. The growing importance of defective delinquency, appreciation of its earlier and adult manifestations, and proper provision for this class, as well as for the feeble-minded, was one of the most urgent demands upon the State at the present time.

Dr. WILLIAM A. WHITE spoke of traditions being broken down, of the practical results increased insight into abnormal behavior had brought about, and the importance of developing and restoring the working capacity of a delinquent individual; a new era in the understanding of human conduct was opening, and the problem of insanity and criminology was much the same.

Dr. JOHN T. MACCURDY inquired relative to the co-operation of prisoners.

Dr. GLUECK replied that there was an almost unbelievable willingness on their part to cooperate.

Dr. ADOLF MEYER spoke of the value of humanized psychiatry, of a proper atmosphere, and the leading influence of the personality of the worker. He was sure a wider presentation of such concrete material would eventually influence judges to distrust present methods alone and make them recognize the value of more unbiased and significant facts as obtained by this broader and impartial approach.

Dr. CHARLES L. DANA spoke of the value a psychiatric clinic might have if attached to the schools and enlisting the interest of teachers in applied psychology.

Dr. L. PIERCE CLARK spoke of the clinics in connection with the ungraded class system of the public schools and the possibility of correction of relatively benign disorders of conduct at their inception as a prophylactic measure in handling many of the antisocial tendencies that might ultimately lead to criminal careers if not corrected.

Dr. GLUECK concluded by telling of a recent dinner attended by forty graduates from the recent Sing Sing régime, their appreciation of what had been done for them, and their approved attitude toward life.

Stated Meeting Held February 7, 1917.

DR. L. PIERCE CLARK, PRESIDENT, IN THE CHAIR.

Nervous States and Nervous Attacks in Children.—Dr. C. MACFIE CAMPBELL, Associate Professor of Psychiatry, Johns Hopkins Hospital, read this paper. By means of a large, well summarized case material, the speaker illustrated special types of neurotic reactions prevalent in childhood and the probable physiological levels from which they had their origin. These reactions were faulty adaptations to a complex environment, which were inferior and unhygienic, analyzable, and to great extent open to reeducational modification. Of the various reactions specified there were pallors, fainting attacks, narcoleptic states, spasmophilic reactions, and convulsive phenomena. Apt cases were cited, showing sometimes the apparent comparative simplicity, more often the complexity of the biological forces at work provoking these reactions. The utilization of these nervous states and attacks to meet conflicts and unpleasant situations and to obtain desired results was striking. Further study on these disorders might enable us to formulate the constitutional inferiority of the individual in definite biochemical and physiological terms. The importance of taking a wider psychobiological attitude for the understanding of neurotic symptoms was urged.

Dr. WILLIAM A. WHITE spoke of the enlightening value work of this character should have on the adult situation and the importance of carrying the analysis further. He would like to see the material worked with special reference to libido trends and earlier fixations. The conscious levels could be worked out readily, but the archaic were difficult to investigate. The problem was a teleological one.

Dr. E. E. Southard wondered if the mental causes were really very complex after all, and not more genetic than etiological. What was somatic and what was functional was a question of preponderance.

Dr. Campbell replied that adaptation to life was a matter of considerable complexity and a faulty reaction might thus occur, but agreed that there were many levels to be worked at in the fuller understanding of these reactions.

Dr. Stewart Paton spoke of certain biochemical experiments on embryos showing the effect of absence of calcium salts in determining excitability. The speaker, in this connection, alluded to the early developmental appearance of the thyroid and adrenal glands, and their connection with the autonomic and sympathetic nervous systems and appearance of related crises; for example, gastric and perhaps epileptic phenomena might be related to a disturbed balance herein, the conscious and unconscious phenomena being quite secondary.

Dr. L. Pierce Clark spoke of the neurotic syndromes in childhood as being more elementary and elusive for clinical grasp than the same syndromes in the adult, hence the difficulty in handling and formulating the significance of the former for diagnostic and therapeutic purposes. They probably furnish a more favorable opportunity for correction and riddance before they become definite and fixed disorganizations of habits. The suggestions of the paper ought to be of greatest value to parents, who often do not recognize these minor and elusive psychopathic traits as being worthy of attention. The same consideration ought to be given these traits by both physicians and social workers who, being unbiased, can be of greatest assistance to help the child to make an adaptation in its developmental life which oftentimes the parents are unable or unwilling to do.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Medical Council of Canada

Montreal, October 10, 11 *and* 12, 1916.

ANATOMY

1. Describe the urinary bladder, including its attachments, its blood and nerve supply.
2. Describe the nasal fossæ and adjoining air sinuses.
3. Give fully the location and relations of the spleen.
4. Describe accurately the origin, course, relations, and terminations of a typical intercostal artery.
5. Describe the radiocarpal joint, including bones, ligaments, synovial membrane, movements, and relations.
6. Give fully the relations of the trachea.

PHYSIOLOGY.

1. Describe the mechanism which brings about the reflex secretion of submaxillary saliva. What are the histological differences between an active and a resting salivary gland?
2. Describe the effect of fatigue upon the contraction of skeletal muscle, drawing muscle curves to elucidate your answer. Discuss the cause of muscular fatigue.
3. How is blood pressure measured in the human being? Explain by what means general blood pressure may be raised and lowered, and also how local blood pressure may be altered.
4. Describe the structure of the skin. Explain how the different sensory areas of the skin have been mapped out. Trace the pathway of the different nerve impulses from the skin areas to the cerebral and cerebellar cortex.
5. Distinguish the different kinds of white blood cells and specify their function.
6. What changes does the uterus undergo during menstruation?

PATHOLOGY AND BACTERIOLOGY.

1. What is meant by agglutinins, precipitins, opsonins, and anaphylaxis?
2. What do you understand by edema, anasarca, ascites? What are the causes of these conditions?
3. Describe fully the morbid changes in the lungs in (*a*) acute lobar pneumonia, and in (*b*) acute lobular pneumonia.
4. Give the pathological-anatomical forms of acute endocarditis, their situation, and their pathogenesis.
5. Write what you know of the *Bacillus diphtheriæ*.
6. What are "carriers"? Mention the diseases that are admittedly due to the influence of the "carrier"?

ANSWERS.

ANATOMY.

1. The *urinary bladder* is a hollow musculo-membranous viscus, situated chiefly in the pelvic cavity, but when fully distended it extends into the abdominal cavity. It lies behind the pubes and the rectum in the male, and between the pubes and cervix uteri and upper part of the vagina in the female. On the inside, three openings are observed, the two ureteral openings behind and that of the urethra in front; the space between these openings is called the trigone. The peritoneum covers the superior surface of the bladder and extends for a variable distance over the anterior surface; that part of the anterior surface which is not covered by peritoneum is called the prevesical space of Retzius. Most of the posterior surface is covered by peritoneum. The *attachments* are a number of ligaments, five true and five false ones; the true ones are two anterior or puboprostatic, from the back of the os pubis to the front of the neck of the bladder; two lateral, which are expansions of the pelvic fascia; and the urachus, extending between the summit of the bladder and the umbilicus. The false ligaments are peritoneal folds; two posterior, from the back of the bladder to the rectum in the male and the uterus in the female; two lateral, from the iliac fossæ to the sides of the bladder; and one superior, from the summit of the bladder to the umbilicus. In addition, the bladder is attached to the ureters, urethra, and rectum; also to the prostate in the male, and to uterus and vagina in the female. The *arteries* are the superior, middle, and inferior vesical, and branches from the obturator and sciatic, all from the internal iliac; in the female, there are additional branches from the uterine and vaginal arteries. The *veins* form plexuses around the neck, base, and sides of the bladder, and end in the internal iliac vein. The nerves are derived from the hypogastric plexus of the sympathetic, and from the third and fourth sacral nerves.

2. The *nasal fossæ* are two irregular cavities situated in the middle of the face. They open in front by the anterior nares, and behind into the nasopharynx by the posterior nares. They are separated by the septum, which is generally deviated to one side. The mucous membrane lining the nasal fossæ is called the Schneiderian membrane. Each fossa has a roof, a floor, an inner and an outer wall. From the outer wall there project into each fossa the superior and middle turbinated processes of the ethmoid bone, and the inferior turbinated bone; these bony processes divide each fossa into a superior, middle, and inferior meatus. The nasal fossæ communicate with the sphenoidal sinus, the anterior and posterior ethmoidal cells, the frontal sinus, and the antrum of Highmore.

The *roof* is formed by the ethmoid, nasal, frontal, sphenoid, vomer, and palate bones; the *floor* is formed by the maxillary and palate bones; the *outer wall*, by the nasal, maxillary, lacrymal, ethmoid, inferior turbinated, palate, and sphenoid bones; the *inner wall*, or *septum*, by the ethmoid, vomer, frontal, nasal, sphenoid, maxillary and palate bones, and septal cartilage.

The *antrum of Highmore* is situated in the body of the superior maxillary bone, is pyramidal in shape, its apex being at the malar process and its base forming the external wall of the nasal cavity. Above it is covered by the orbital surface of the maxilla, and below by the alveolar border. Its walls are lined with mucoperiosteum which is continuous with the mucous membrane of the middle meatus of the nose.

The *frontal sinus* is found between the two layers of bone in the vertical part of the frontal bone. The two sinuses are separated by a thin septum. The cavity is lined with mucoperiosteum which is continuous with the middle meatus of the nose.

The *ethmoidal cells* are situated in the lateral mass

of the ethmoid bone; the anterior cells open into the middle meatus of the nose, and the posterior cells into the superior meatus.

The *sphenoidal sinuses* are situated in the body of the sphenoid bone immediately below the fossa which lodges the pituitary body; they are separated by a septum, and open into the superior meatus of the nose.

3. The *spleen* is situated in the upper and left side of the abdominal cavity; it lies far back in the left hypochondriac region, behind the stomach. It lies above the left kidney and the splenic flexure of the colon. It is surrounded by peritoneum except at the hilum. Above and externally are the peritoneum, diaphragm, left ninth, tenth and eleventh ribs, left lung and pleura, and posterior thoracic muscles. Below, the splenic flexure of the colon, costo-colic ligament, and (sometimes) the tail of the pancreas. Internally, the stomach (posterior surface of the fundus), left kidney and suprarenal capsule, and tail of the pancreas.

4. Intercostal arteries. "(*a*) The *vertebral portions* of the intercostal arteries, arising in pairs from the posterior part of the thoracic aorta, pass around the vertebræ—the right being covered by thoracic duct, vena azygos major, pleura, lung, esophagus—the left, by vena azygos minor, left superior intercostal vein, third vena azygos, pleura, lung. The arteries here divide into posterior or dorsal, and anterior or intercostal branches. (*b*) The *intercostal portions* run forward and obliquely upward in the intercostal space to the lower border of the superior rib, and divide near the angle of the rib into the upper (larger) and lower (smaller) branches—the former, to run in the groove along the lower border of the upper rib and anastomose with the superior intercostal branch of the internal mammary in the upper spaces, and of the musculophrenic in the lower—the latter, to run along the upper border of the lower rib and anastomose with the inferior branch of the internal mammary in the upper spaces, and of the musculophrenic in the lower. At first these arteries lie between pleuræ, lungs, endothoracic fascia, and infracostals internally—and external intercostal muscles externally—then (from the angles of the ribs) between the external and internal intercostal muscles. The sympathetic nerve crosses them opposite the head of the ribs. The intercostal vein lies above and the intercostal nerve below the intercostal arteries—except in the upper spaces."—(Bickham's *Operative Surgery.*)

5. The *radiocarpal joint* is formed by the under surface of the radius and a triangular plate of fibrocartilage, which together form a shallow socket for the scaphoid, semilunar, and cuneiform bones. The ulna does not take part in this articulation. The ligaments are the anterior, posterior, internal and external. The *anterior ligament* extends from the lower border of the inferior extremity of the radius, and is inserted below into the scaphoid, semilunar, and cuneiform bones. The *posterior ligament* arises from the posterior aspect of the lower end of the radius and is inserted into the scaphoid, semilunar, and cuneiform bones. The *external lateral ligament* extends from the tip of the styloid process of the radius to the scaphoid bone. The *internal lateral ligament* extends from the styloid process of the ulna to the cuneiform and pisiform bones. These ligaments are continuous with each other, and so form a capsule around the joint. The synovial membrane lines the deep surfaces of the ligaments, it is loose and lax and presents numerous folds. The *movements* are those of flexion, extension, abduction, adduction, and circumduction. *Anterior* to the joint are the flexor carpi radialis, palmaris longus, flexor carpi ulnaris, flexor sublimis digitorum, flexor profundus digitorum, and flexor longus pollicis. *Posteriorly*, extensor carpi radialis (longior and brevior), extensor communis digitorum, extensor indicis, extensor minimi digiti, extensor carpi ulnaris. *On the radial side*, the supinator longus, extensor ossis metacarpi pollicis, extensor brevis pollicis, extensor longus pollicis.

6. Relations of the trachea. *In the neck. Anteriorly*, the skin, superficial fascia, anterior jugular veins, inferior thyroid veins, thyroidea ima artery, sternohyoid and sternothyroid muscles, isthmus of thyroid gland, thymus or its remains. *Posteriorly*, the esophagus. *Laterally*, the lateral lobes of the thyroid gland, inferior thyroid arteries, recurrent laryngeal nerves, and the sheath containing the common carotid artery, internal jugular vein and pneumogastric nerve. *In the thorax. Anteriorly*, upper part of sternum, sternohyoid and sternothyroid muscles, thymus or its remains, left innomimate vein, transverse part of the arch of the aorta, innominate artery, left common carotid artery, deep cardiac plexus, and left recurrent laryngeal nerve. *Posteriorly*, the esophagus. *Laterally*, the pleuræ, pneumogastric nerves.

PHYSIOLOGY.

1. The salivary glands have a double nerve supply, from the sympathetic and from the cranial nerves. The submaxillary gland receives its sympathetic fibers from branches of the cervical sympathetic which ramify on the facial artery, and its cranial fibers from the chorda tympani nerve. These fibers run for a short time with the lingual nerve, and then leave it as a slender nerve which, reaching Wharton's duct, runs along this to the gland. The fibers are connected in the hilus of the gland with nerve cells. A small collection of nerve-cells—the submaxillary ganglion—is found in the triangle between the chorda tympani nerve, lingual nerve, and duct. Different effects are obtained according as the chorda tympani or the sympathetic fibers are stimulated. Stimulation of the chorda tympani in the dog gives rise to an active dilatation of the vessels of the gland, and a copious watery secretion containing only a small amount of mucin and formed elements. Stimulation of the sympathetic causes constriction of the vessels and a scanty flow of very thick viscid saliva, rich in mucin and formed elements. The changes that occur in the cells are much more marked under sympathetic than under chorda stimulation. In consequence of the differences in the action of these two sets of nerve fibers, they have been supposed to have two distinct functions. The chorda fibers are vasodilator and secretomotor of water; the sympathetic fibers are vasoconstrictor and secretomotor of organic matter. According to Langley the action of the gland fibers of the sympathetic and the chorda tympani nerve are probably identical, the differences in the saliva obtained by the stimulation of the two sets of nerves being conditioned by the concomitant vascular changes. Against this view may be urged the fact that while atropine paralyzes the secretory fibers of the chorda tympani, it has practically no effect on those derived from the sympathetic. The center for the secretion of saliva is located in the medulla. In the resting condition of the gland, the acini are seen to be distended with large cells having clear hyaline contents, so close together that no lumen can be seen. The nuclei situated at the outer border of the cells, near the basement membrane, appear shriveled, with irregular margins. In a gland that has been actively secreting for some time, the acini and the cells are smaller, the lumen quite distinct, and the nuclei round and swollen. The section appears darker from the fact that the cells have taken up the staining fluid more readily.—(From Starling's *Elements of Human Physiology.*)

2. *Effect of fatigue upon the contraction of skeletal muscle*: "At first the contractions improve, each being a little higher than the preceding; this is known as the beneficial effect of contraction, and the graphic record is called a staircase. Then the contractions get less and less. But what is most noticeable is that the curves are much more prolonged; the latent period gets longer; and the period of relaxation gets very much longer; this condition is known as contracture, so that the original base line is not reached by the time the next stimulus arrives. In the last stages of fatigue, contracture passes off. Contracture is often absent in fatigue of mammalian muscle. *Cause of muscular fatigue:* This is due to the consumption of the substances available for the supply of energy in the muscle, but more particularly to the accumulation of waste products of contraction; of these sarcolactic acid is an important one. Fatigue may be artificially induced in a muscle by feeding it with a weak solution of lactic acid, and then removed by washing out the muscle with salt solution containing a minute trace of an alkali. If the muscle is left to itself in the body, the blood stream washes away the accumulation of acid products, and fatigue passes off."—(Halliburton's *Physiology.*)

3. Blood pressure is estimated by means of a sphygmomanometer.

"The individual whose blood pressure is about to be recorded should be placed in such a position that his heart, the artery the blood pressure of which is to be determined, and the manometer are at the same level. It is usual to record the pressure in the brachial artery. The india-rubber bag of the instrument should be wrapped around the bared arm, the metal covering of the bag should then be adjusted, and firmly strapped in position. The india-rubber tube leading from the bag is then adjusted to the proximal limb of the U-shaped manometer which contains mercury. The experimenter places the index finger of his left hand over the radial pulse of the subject, and with his right hand he compresses the syringe and so drives air into the india-rubber tube and the india-rubber bag around the individual's arm. The pressure of the air in the bag around the arm is recorded by movement of the mercury from the proximal to the distal limb of the manometer. The operator keeps on pressing the syringe until oscillatory movements are seen at the surface of the mercury in the distal limb of the manometer; the mean point of maximum oscillations registers the diastolic pressure. If the pressure in the bag is still further increased, the oscillations diminish in amplitude and finally disappear, and at this point the pulse can no longer be felt at the wrist. The height of the mercury supported then registers the amount of systolic pressure. It will then be noted that the mercury has descended in the proximal limb of the manometer, and has ascended in the distal limb of the manometer; the difference between the two mercurial levels will be the blood pressure of the brachial artery. The normal systolic pressure in man is about 120 mm. Hg, and the diastolic pressure about 100 mm. Hg. In women the pressures are about 10 per cent. less. In children the systolic pressure may be as low as 90 mm. Hg, with a diastolic pressure of about 80 mm. Hg."—(R. Hutchison.)

General blood pressure may be *raised* by increase in the rate and power of the heart beat, increase in the contraction of the arterioles, or increase in the volume of the blood. It may be *lowered* by the opposite conditions.

Local blood pressure may be altered by the increase or decrease in the size of the arterioles in areas other than the one under investigation.

4. "The skin is composed of a deep portion, the corium, derma, or true skin; and of a superficial portion, the epidermis or cuticle.

The *corium* makes up by far the greater part of the skin, and within it are the perspiratory glands, the sebaceous glands, the hairs, together with both blood and lymphatic vessels. The upper surface, where it joins the epidermis, is irregular, being composed of elevations—papillæ—and intervening depressions. In some of these papillæ are the tactile corpuscles, in which nerve-fibers end.

The *epidermis* is made up of a deep and a superficial layer. The deep layer (rete mucosum or rete Malpighii) covers the papillæ of the corium and fills the depressions between them. It is composed of cells, round or of different shapes due to pressure of contiguous cells, the material of which they are composed yielding readily. It is in this layer that the pigment is deposited which characterizes the dark races. The superficial layer of the epidermis is composed of cells which are flat and dry or horny."—(Raymond's *Physiology.*)

"The surface of the skin appears to be divided into innumerable small sensory areas, separated by intervals which are not responsive to those stimuli which are only just above liminal intensity. Each of these small areas responds to a specific adequate stimulus, such as pressure, heat, cold, pain. No doubt each area contains a special sensory end organ. The pressure spots, heat spots, cold spots, and pain spots are intermingled, but in some regions one variety predominates, in other regions another variety predominates. The distribution of these spots is by no means uniform. . . . The responsiveness of the skin to external stimuli is investigated by esthesiometers. Pressure sense is estimated by little weights placed upon the skin. Heat and cold sense is investigated by the use of hollow pencil-shaped rods containing hot and cold water respectively, or by using minute drops of water at different temperatures as stimuli. Pain sense is investigated by the use of fine needles. . . . The finer uncrossed tactile sensations pass into the cord at the posterior root zone, and travel up in the column of Burdach and column of Goll. For the most part the impulses from the leg pass up the column of Goll, and those from the arm up the column of Burdach. . . . The coarser tactile sensations, along with the sensations of heat, cold, and pain, travel into the posterior gray cornua, thence into the central gray matter, crossing the cord at the anterior gray commissure. The fibers which convey these impulses appear to make cell stations at the base of the opposite posterior cornua, and from some of these posterior cornual cells new fibers arise which conduct these impulses up the spinal cord through the spinothalamic tract. These impulses eventually arrive at the optic thalamus, and by the thalamo-cortical fibers gain the gray matter of the cerebral cortex. The nerve fibers from the spinal cord, which convey the impulses which eventually give rise to sensations of heat, cold, and pain, travel up through the medulla, external to the olivary body, and in this region they mix with the fibers coming up from the tract of Gowers. Both these sets of fibers eventually reach the optic thalamus."—(From Lyle's *Manual of Physiology.*)

5. *Varieties of white blood cells:* (1) *Small mononuclear leucocytes* or *lymphocytes*, which are a little larger than red blood cells and consist of a narrow zone of protoplasm around a relatively large and circular nucleus; both nucleus and protoplasm are basophilic; this variety is about 25 per cent. of the total colorless corpuscles. (2) *Large mononuclear leucocytes*, which consist of a relatively small oval nucleus in the center of basophilic protoplasm; the diameter is about 12 to 20 microns, and they constitute about 1 per cent. of total white corpuscles. (3) *Transitional leucocytes*, which consist of a smaller cell body than the last, the protoplasm is basophilic and granular, and the nucleus is oval or lobed; they make up about 2 to 4 per cent. of the white cells. (4) *Polynuclear leucocytes*, which make up the chief mass of white cells, being about 70 per cent. of the whole; they are about 9 to 12 microns in diameter, and have several nuclei, of different shapes, which are basophilic and granular; the protoplasm is finely granular, and stains with neutral stains and also faintly with acid (eosin) stains. (5) *Eosinophile leucocytes*, which are usually about 12 to 15 microns in diameter and contain two or three nuclei or one nucleus of irregular shape; the protoplasm is granular, and readily stains with eosin or other acid stains; they are about 2 per cent. of the white corpuscles.

Their *functions* are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

6. *Changes in the uterus during menstruation.* "The endometrium, in the four or five days preceding the flow, becomes rapidly thicker and its superficial layers are congested with blood and, in places, small collections of blood may be noticed. Opinions differ very much as to the change undergone by this thickened membrane during the flow. According to some authors, most of the membrane is thrown off and the blood escapes from the denuded surface mixed with pieces of the membrane. According to others, no material destruction of the membrane occurs, the blood that escapes being due to small capillary extravasations or perhaps mainly to a process of diapedesis. It would seem that the amount of destruction of the endometrium must be subject to individual variations. After the cessation of the flow the mucous membrane is rapidly repaired by regenerative changes in the tissues; the surface epithelium, if denuded, is replaced by proliferation of the cells lining the uterine glands and the thickened, edematous condition of the membrane rapidly subsides during a period of six or seven days. The mucous membrane of the uterus may be said to exhibit a constantly recurring menstrual cycle which falls into

four periods: (1) Period of growth in the few (five) days preceding menstruation, characterized by a rapid increase in the stroma, blood vessels, epithelium, etc., of the membrane. (2) The menstruation or period of degeneration (four days) during which the capillary hemorrhage takes place and the epithelium suffers degenerative changes and is cast off more or less. (3) The period of regeneration (seven days) during which the mucous membrane returns to normal size. (4) The period of rest (twelve days) during which the endometrium remains in a quiescent condition."—(Howell's *Text-book of Physiology.*)

PATHOLOGY AND BACTERIOLOGY.

1. *Agglutinins* are antibodies which cause certain bacteria, when suspended in a fluid, to form clumps.

Precipitins are specific antibodies which develop in the serum of animals inoculated with bacteria and which produce a precipitate in a clear solution of the particular culture filtrate against which the animal has been immunized.

Opsonins are substances in normal and immune sera which act upon bacteria and render them more readily available for being ingested by phagocytes.

Anaphylaxis is a condition of hypersusceptibility induced by the injection of a serum. It is (to some extent) the opposite of prophylaxis, and in place of rendering the person injected immune the serum renders him particularly susceptible.

2. *Edema* is an excess of transuded fluid in the interstices of the tissues. When such fluid infiltrates the subcutaneous tissues the condition is called *anasarca.* A collection of such fluid within the abdominal cavity is called *ascites.*

Six factors enter into the production of edema, usually more than one acting at a time, viz., positive pressure in the vessels (in proportion as it rises), permeability of the vessel wall, osmosis from excess of salts outside the vessel as seen in the action of a saline laxative, selective action of the endothelium, variations in the blood plasma, and obstructed onflow in the lymph channels.

3. ACUTE LOBAR PNEUMONIA. "It is convenient to describe four stages, those, namely, of (1) hyperemia or engorgement, (2) red hepatization, (3) gray hepatization, and (4) resolution. *First stage or splenization.*—The lung is injected, dark red, and heavy, and pits under the finger; on pressure, there exudes a frothy serum tinged with blood and slightly aërated. The lung still floats in water. *Second stage or red hepatization.*—The part involved is solid and friable, presents a granular or red granite appearance, and sinks in water. The alveoli are filled with a coagulated exudation, which shows under the microscope fibrin, leucocytes, red corpuscles, proliferated alveolar epithelium, and pneumococci. *Third stage or gray hepatization.*—The lobe has now the appearance of gray granite, the lung substance is softer and more friable; on pressure, a dirty purulent fluid exudes. The gray appearance is due to four factors: (1) Decolorization of the red blood corpuscles; (2) obliteration of the alveolar blood vessels from pressure; (3) fatty degeneration of the coagulated material; (4) great infiltration of leucocytes. A more advanced stage, in which the lung tissue is bathed in purulent fluid, is known as purulent infiltration. It is probably inconsistent with life. *Fourth stage or resolution.*—Resolution of the inflammatory exudation is brought about principally by absorption (autolysis), but partly by liquefaction and expectoration. Pneumonia may affect a lobe, or the whole of a lung, or it may attack both lungs. Double pneumonia occurs in about 10 per cent. of cases. Different parts of the same lung may at the same time show different stages. There is always some degree of pleural inflammation over the affected area. Modern enlargement of the spleen is very common."—(Wheeler and Jack's *Practice of Medicine.*)

ACUTE LOBULAR PNEUMONIA. "The disease affects both lungs, and begins in the terminal bronchioles, spreading thence to the infundibula and alveoli. The consolidated patches have therefore a lobular arrangement, but if many adjacent lobules are affected the consolidation may be almost lobar. The bronchioles are inflamed and frequently plugged with mucus, and their walls and the surrounding interstitial tissue are infiltrated with small cells. The walls of the air vesicles in the consolidated area are congested, their epithelium is swollen, and their lumen is filled with proliferated epithelial cells, leucocytes, and a mucous or mucopurulent (not fibrinous) exudate. Many lobules are collapsed, but not inflamed, from plugging of the bronchioles. When cut into, the small consolidated areas are seen to be conical in shape, with their bases towards the pleura, reddish in color, with indefinite margins, and separated from each other by crepitant lung tissue. Adjacent lobules may be emphysematous (compensatory emphysema). The bluish-gray collapsed areas are most numerous in the lower lobes."—(Wheeler and Jack's *Handbook of Medicine.*)

4. ENDOCARDITIS.

Types: I. Acute { Simple / Malignant or Ulcerative { Septic / Typhoid / Cardiac }

II. Chronic.

The difference between simple and malignant endocarditis is probably one of degree rather than of kind.

Etiology: Simple endocarditis is associated with rheumatism or scarlet fever. Malignant endocarditis is also associated with rheumatism, scarlet fever, and also with pneumonia or septic processes. Micrococci are often found. Chronic endocarditis may follow an acute endocarditis, or may be the result of syphilis, old age, high arterial tension, gout.

Morbid anatomy: In the simple form there will be found a cloudiness, followed by edematous thickening of the valvular endocardium; superficial erosions, and the formation of small granulations; deposits of layers of fibrin and corpuscles from the blood, the whole process resulting in the formation of small warty vegetations. These vegetations are most marked at a slight distance from the free borders of the valves—*i.e.* those parts which come into opposition during closure. In course of time they are transformed into fibrous tissue. According to Poynton and Paine the infective organisms are conveyed to the base of the valves by the capillaries, and thence pass to the subendothelial tissues by the minute nutrient channels in the valvular substance; others hold that the organisms are derived from the blood circulating over the surface of the valves. In the malignant form the initial changes are similar, but there are some important differences, inasmuch as ulcerations may completely replace the vegetations. The differences are: (1) The vegetations when present are larger and fungating. (2) The underlying tissues are necrotic and show loss of substance and round-celled infiltration. (3) They contain masses of micrococci, while in simple endocarditis the organisms are scanty. The two forms cannot be distinguished by the organisms producing them; either simple or malignant endocarditis may arise from a pyogenic infection. (4) When the vegetations become detached they form *septic* emboli, giving rise to metastatic abscesses. (5) The ulcerative process causes great destruction of the valves, and may even lead to perforation of the curtains. (6) The subsequent or permanent changes in the valves, if the patient survive, are much more marked. (7) If the vegetation touches the mural endocardium as it flaps to and fro, the part touched becomes affected by contact.

As regards the side of the heart most affected—*Congenital* endocarditis attacks the right side of the heart (but note that many congenital cardiac lesions are due not to endocarditis, but to developmental faults); simple endocarditis attacks the left only; the *malignant* attacks *both sides*, though the *left* is much more implicated than the right side.

The vegetations are upon that side of the valve opposed to the blood-stream—viz., at the aortic valve the vegetations project into the ventricle, at the mitral valve into the auricle.

As in pericarditis, the myocardium almost always shares in the inflammatory affection.—(Wheeler and Jack's *Practice of Medicine.*)

5. The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 microns in length and from 0.2 to 1.0 micron in breadth, are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aerobic; they are noted for their pleomorphism; they

do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue; they grow well on blood serum, slowly on gelatin, and with difficulty on potato.

6. *Carriers* are persons who, though apparently well, harbor within their bodies and distribute to their environment pathogenic bacteria. Diseases thus "carried" are: Typhoid, diphtheria, meningitis, tetanus, malignant edema, Asiatic cholera, dysentery, and perhaps poliomyelitis and other diseases.

(*To be continued*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

CASE HISTORIES IN OBSTETRICS. Groups of cases illustrating the fundamental problems which arise in obstetrics. By ROBERT L. DENORMANDIE, A.B., M.D., F.A.C.S. Second Edition. Published by W. M. Leonard, Boston, Mass. 1917. 516 pages.

DISEASES OF THE STOMACH, INTESTINES AND PANCREAS. New (third) Edition Revised. By ROBERT COLEMAN KEMP, M.D. Octavo of 1096 pages, with 438 illustrations. Published by W. B. Saunders Co., Philadelphia and London. 1917. Cloth, $7.00 net; half morocco, $8.50 net.

DISEASES OF THE GENITOURINARY ORGANS AND THE KIDNEYS. Fourth Revised Edition. By ROBERT H. GREENE, M.D. Octavo of 666 pages, 301 illustrations. Published by W. B. Saunders Co., Philadelphia and London. 1917. Cloth, $5.50 net; half morocco, $7.00 net.

PRINCIPLES OF PHARMACY. Second Edition Revised. By HENRY V. ARNY, Ph.G., Ph.D. Octavo of 1056 pages, with 267 illustrations. 1917. Cloth, $5.50 net. Published by W. B. Saunders Co., Philadelphia and London.

LIFE OF DR. LYMAN SPALDING. By his grandson, Dr. JAMES ALFRED SPALDING. 379 pages. 1916. Price, $3.50. Published by W. M. Leonard, 101 Tremont Street, Boston, Mass.

THE METHOD OF ENZYME ACTION. By JAMES BEATTY, M.A., M.D., D.P.H., with introduction by Prof. E. H. STARLING, M.D., Sc.D., F.R.S. 143 pages. Price, $1.75 net. Published by P. Blakiston's Son & Co., Philadelphia, Pa. 1917.

EYE, EAR, NOSE AND THROAT. A Manual for Students and Practitioners. By HOWARD CHARLES BALLINGER, M.D., and A. G. WIPPERN, M.D. New second edition, thoroughly revised. Illustrated with 180 engravings and 8 colored plates. 503 pages. Price, $3.50. Published by Lea & Febiger, 706 Sansom Street, Philadelphia, Pa. 1917.

TWELFTH ANNUAL REPORT OF THE BOARD OF MANAGERS OF THE MANHATTAN STATE HOSPITAL TO THE STATE HOSPITAL COMMISSION. For the nine months ending June 30, 1916. 88 pages. Published by J. B. Lyon Co., Albany, N. Y. 1917.

THE SURGICAL CLINICS OF CHICAGO. April, 1917. Vol. 1, No. 2, with 99 illustrations. 448 pages. $10.00 per year. Published bi-monthly by W. B. Saunders Co., Philadelphia and London.

FIRST ANNUAL REPORT OF THE STATE DEPARTMENT OF HEALTH OF MASSACHUSETTS. 826 pages. Published by Wright & Potter Printing Co., State Printers, Boston, Mass. 1916.

FOOD POISONING. By EDWIN OAKES JORDAN. 115 pages. Illustrated. Price, $1.00 net postage. Published by The University of Chicago Press, Chicago, Ill.

THE TREATMENT OF TABETIC ATAXIA. By means of systematic exercise. By Dr. H. S. FRENKEL. Second revised and enlarged English edition by L. FREYBERGER, J.P., M.D. (Vienna). With 130 illustrations. 209 pages. Price, $3.00 net. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

SPINAL INVESTIGATION OF POLIOMYELITIS. Report of committee appointed by the Mayor to cooperate with the Department of Health. ALVAH H. DOTY, M.D., Medical Director. New York, 1917.

Therapeutic Hints.

Treatment for Erysipelas.—Critzman has used the following with good results: Picric acid solution 1 to 1,000 with 12 grams of alcohol added to the liter is painted over the diseased area and a dry cotton dressing applied. This should be repeated every twelve hours. The eruption is usually checked in three days with a reduction in temperature and improvement in general conditions.

Fever.—Fischer advises the use of the following in cases where the fever is very high and a diagnosis has not been made:

℞ Sweet spirit of niter.....1½ fluidrachms
Citrate of potassium.....30 grains
Syrup of lemon.....4 fluidrachms
Water to make.....2 fluidrachms

A teaspoonful every three hours, for child of one year of age. —*Diseases of Infancy and Childhood.*

Pruritus.—Whitla has found that the accompanying formula will give relief when the itching is caused by a neurosis:

℞ Ext. cannabis ind.....gr. vi
Acid. carbolici.....gr. xviii
Cocain. hydr.....gr. vi
Ext. gelsemii.....gr. vi

M. et fiant pil. xxiv. Sig.: One every night.—*Dictionary of Treatment.*

Asthma.—Potter offers the following prescription for relief in this condition:

℞ Ext. stramonii.....gr. ij	0.130	gm.
Potass. iodidi.....℥ jss	6.0	gm.
Ammonii carbonatis.....℥ j	4.0	gm.
Tr. lobeliæ.....℥ jss	6.0	gm.
Aquæ chloroformi q.s. ad. ℥ viij	480.0	gm.

M. S.—Tablespoonful every six hours.—*Hughes' Practice of Medecine.*

Treatment of Bronchopneumonia in Children.—Measham advocates the following method of procedure in this condition: The child's chest is wrapped in a light Gamgee jacket, and over this is worn a pair of woolen combinations. The room is to be kept warm, but the windows are always open; no draughts, however, are allowed to blow on the patient. The child is encouraged to take frequent sips of cold water. No medicines are given by mouth, but a subcutaneous injection of quinine hydrochloride is given morning and evening. A solution is prepared in which one grain of the quinine salt is dissolved in ten minims of water, and the dosage given as follows: For a child of six months, 5 minims; one year, 10 minims; two years, 15 minims; and over two years, 20 minims. A striking feature is the rapidity with which physical signs of the disease disappear, the patient often appearing in normal health ten days after the first injection.—*The Practitioner*, June, 1917.

Nervous Exhaustion.—Goodell found the following formula efficacious for the relief of this condition:

℞ Extracti sumbul.....gr. xx (1.3)
Ferri sulphatis.....gr. xx (1.3)
Asafetidæ .....gr. x (0.60)
Arseni trioxidi.....gr. ½ (0.03)

Fiant pilulæ No. xx.

S.—One three times a day after meals.—*Hare's Practical Therapeutics.*

POLIOMYELITIS.

BY ALVAH H. DOTY, M.D.,

NEW YORK.

THE special investigation of poliomyelitis conducted during the past year by a committee appointed by the Mayor of the City of New York, and supported by the Rockefeller Foundation, has added much valuable data to the epidemiological history of this disease, and has gone far to sustain the opinions of previous investigators of this subject—notably Wickman, who presented to the public a most important and exhaustive report regarding an epidemiological study of the outbreak of poliomyelitis which occurred in Sweden during 1905. A careful analysis of the material collected in connection with these researches leaves no reasonable doubt that poliomyelitis is transmitted by personal contact through the medium of discharges containing the specific organism of this disease.

No epidemiological investigation ever undertaken has presented such impressive and extended evidence bearing upon the frequency with which infectious diseases are transmitted by mild, ambulant, or unrecognized cases as that furnished by the investigation of the Mayor's Committee. The importance of this cannot be overestimated, for it explains various disputed points in connection with outbreaks of poliomyelitis.

While many theories have been presented, no proof is forthcoming that poliomyelitis is transmitted by insects, general food supplies, aerial conveyance, clothing, or innumerable other articles. Erroneous theories are constantly being offered concerning media of infection, and are largely responsible for the extension of communicable diseases, for they not only seriously interfere with a proper concentration of effort in dealing with the true source of infection, but undue consideration of these theories on the part of health officials and others prevents efficient public co-operation, which is so urgently needed in dealing with outbreaks of infectious diseases.

The belief that infectious diseases are transmitted over long distances by the air, by clothing, money, and the like, is very popular and readily accepted, for it supplies a convenient and plausible explanation for the appearance of an infectious disease at any time or place when the real cause of the outbreak is unknown or has not been carefully sought for. Besides such theories are quite inviting, for they do not involve much personal responsibility. On the other hand, when a disease is known to be transmitted by personal contact, there must be a careful and painstaking investigation to detect the presence of mild as well as marked cases; to discover the true source of infection, and to maintain various necessary protective measures which call for special and individual attention.

The doubt which exists among those who are not yet convinced that poliomyelitis is transmitted by personal contact, is due largely to a statement which has been widely disseminated; that more than one case in a family seldom occurs during a given outbreak of the disease. This statement is misleading and is the result of a superficial investigation of this subject. The truth is that secondary cases of poliomyelitis do occur frequently in the same family and in a manner which presents clear and satisfactory evidence that the infection is transmitted from one person to another. Secondary cases not only occur often in the same family, but sometimes all the children succumb to the disease, and in some instances, the father or mother as well.

The proof which most effectively refutes the statement referred to lies in the fact that the investigation of the Mayor's Committee produced indisputable evidence that in many instances where but one case of poliomyelitis was officially reported in a family, other cases had occurred, although they were not identified until the investigation took place. Proof of this was everywhere present.

The value of this information lies chiefly in the fact that heretofore the medical profession has had but little definite knowledge of poliomyelitis and less of the mild and non-paralytic form and the frequency with which the latter type occurs. As an illustration, it may be stated that of the number of officially reported cases investigated by the Committee twenty per cent. were at first erroneously diagnosed by the attending physician, and in fifty per cent. of these the disease was mistaken for some form of gastrointestinal disturbance.

It is proper to assume that mild or unrecognized cases of poliomyelitis accompany the well marked cases of the disease whenever it appears. Therefore many children are rendered immune unknown to anyone.

Further doubt as to the transmission of poliomyelitis by personal contact is encouraged by reports presented in individual cases, that there was a complete isolation of the patient or the one affected was removed from any possible contact. The answer to this is as follows: (1) This statement is made in connection with all infectious diseases; (2) it emanates chiefly from the family and not as a result of a careful investigation; (3) in order to prove that a disease is transmitted by personal contact, it is not required that the source of infection in all discovered cases shall be established. It is only

needed that proof shall be presented in a reasonable number of cases. It may be said in passing that the communicability of measles by personal contact is not questioned; yet the identity of the organism of this disease, like that of poliomyelitis, is yet undetermined. In both diseases we have satisfactory evidence that the agent of infection is contained in the discharges from the mucous membrane of the nose and throat. In addition there is satisfactory evidence that in poliomyelitis the infectious organisms exist also in the intestinal tract. Unfortunately the latter has not yet received proper attention, at least so far as preventive measures are concerned.

No one who is practically familiar with infectious diseases doubts that there are some unusual means of transmission; and while these should be given proper consideration, it is the common sources of infection which must chiefly engross our attention if we expect to be successful in preventing outbreaks of poliomyelitis or any other infectious disease.

We may conclude that the transmission of poliomyelitis by personal infection is proven, and that the most dangerous medium of infection is the mild and unrecognized case, for, as a rule, such persons are under no control and may convey infection in any direction. Proof is wanting that poliomyelitis is *commonly* transmitted by well persons who act as "carriers," although the latter means of conveyance undoubtedly occurs in poliomyelitis as in the case of other infectious diseases. While it is true that specific organisms are transmitted to others in this way, it is also true that this theory of the transmission of diseases is too frequently accepted. This is due largely to the fact that it offers a plausible explanation for the appearance of an infectious disease, the origin of which cannot be clearly determined. The danger of this lies in the fact that it discourages a careful investigation to disclose the true source of infection, which is commonly a mild or unrecognized case.

The preventive measures in dealing with poliomyelitis are similar to those employed in connection with other communicable diseases; the detection of both well marked and mild or previously unrecognized cases; the observation of all cases of illness associated with these, the diagnosis of which is not clearly defined. It is exceedingly important to determine as far as possible the source of infection in each case. To this is to be added isolation of the patient and the most careful protection against contact with infectious discharges.

These methods of prevention are most successfully employed in the beginning of the outbreak.

The proper observance of the methods above described is quite sure to be successful in dealing with outbreaks of poliomyelitis as well as other infectious diseases, and leaves no excuse for the enforcement of unreasonable and hysterical regulations for the protection of the public during these emergencies.

It will not be out of place to speak at length of a most important factor in the prevention of all infectious diseases and one which unfortunately has received far too little consideration. I refer to the cooperation of the public. It is true that health departments throughout the United States issue bulletins relating to the preservation of health, but these do not reach the people among whom outbreaks of infectious diseases most commonly occur, nor do these bulletins contain information prepared in a simple and concise manner and in various languages in order that they may be understood by all; furthermore, many of the class of people referred to do not read. Welfare societies throughout the country render valuable aid in the dissemination of knowledge concerning the means by which health may be preserved. The press is also active in publishing information upon the subject of public health; but these agents do not convey information of a uniform character issuing always from authoritative sources and which reaches the people who are most urgently in need of this instruction.

The apathy of the public in the presence of an outbreak of infectious disease is not the result of unwillingness to aid in this emergency or of ignorance of the danger which is involved under these conditions, but is due rather to the fact that the public is not familiar with sources of infection and the manner in which it may aid in preventing the dissemination of these diseases.

An unusual opportunity to study this feature of public health protection was presented during the investigation of the Mayor's Committee. The homes of two thousand or more families were visited to obtain the views of these people regarding the means by which infectious diseases are transmitted, and to what extent they were willing to aid in preventing this danger. Those interviewed were principally mothers or other members of the family who remained at home and were responsible for the care and protection of the household. These are the people with whom we must deal in securing cooperation against the transmission of infectious diseases. Their opinions as to media of infection were fantastic and far from the truth. Only a few had received any authentic information upon the subject, although practically all stated that they were anxious to know how they might help in this direction in order to save the lives of their children.

There is abundant evidence that the present methods of educating the public regarding the means by which infectious diseases may be prevented are insufficient and unsatisfactory. Information to be of practical value must come through sources which appeal directly to the confidence of the masses. There is no more effective and valuable agent for this purpose than the trained nurse who visits the home and personally explains the subject. Pastors of churches also constitute a valuable means of conveying the needed information. There is not the slightest doubt that many clergymen would willingly devote a certain length of time to the instruction of those under their jurisdiction along the lines just referred to. Heads of the various associations and orders to which many of the poorer classes belong, particularly foreigners, would also be valuable teachers. Other practical methods may be devised by which information concerning the prevention of disease may be transmitted to those who are in greatest need of this instruction. Furthermore, *the information thus imparted should have the sanction and indorsement of expert practical sanitarians.* By these means the public may be taught to render most valuable assistance and cooperation in the preservation of health, particularly during outbreaks of infectious diseases.

CIVILIZATION AND CHILDREN'S DISEASES.*

By ROWLAND GODFREY FREEMAN, M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF PEDIATRICS, N. Y. UNIVERSITY AND BELL. HOSP. MED. COLLEGE; VISITING PHYSICIAN TO THE ROOSEVELT, FOUNDLING, N. Y. NURSERY, AND CHILD'S HOSPITALS, ETC.

THE influence of civilization on morbidity and mortality in infancy and childhood should furnish most amazing data could the actual morbidity and mortality of uncivilized races be obtained. Such races furnish some hygienic conditions not found among the civilized. They live more in the fresh air— that is, they have poorer facilities for excluding air from their habitations than have the civilized nations. Their occupations being manual they should afford more perfect bodily development for the propagation of their progeny, and the mothers should be better able to nurse their babies than the women living under civilized conditions. Such mothers are free from most of the confining duties of the modern mother, such as service on committees, attending close rooms for lectures and religious services, sewing circles, afternoon teas and balls.

On the other hand, adverse conditions exist that far outweigh these advantages. The absolute lack of medical care, the inability to provide proper artificial feeding in case of lack of breast milk, the unsanitary surroundings with the opportunity for sputum and fecal contamination, and the uncontrolled spread of disease, for in many epidemics children are more susceptible than adults. It will be recalled that in Koch's investigations in Africa he was able to obtain an index of the amount of malaria in any community by examining the blood of a certain number of children. In the days before vaccination smallpox attacked chiefly the young children. In addition to this we have the intentional neglect of some babies, particularly the female children, in certain countries.

In distinction from this condition of things we can say that the intelligent and efficient administration of any community now may well be judged from its infant mortality. It has recently been stated by a Roumanian physician that the infant mortality of that country is 50 per cent.—that is to say, one-half of all the children born in Roumania die before the end of the first year. It is within my recollection that more than one-fourth of the babies born in New York died within the first year, and it is only since the government of the city has been taken out of the hands of corrupt political bodies and administered by intelligent officers that this mortality has materially decreased.

In Russia before the war the infant mortality is stated to have been 26 per cent. The infant mortality before the war was higher in the Central Empires than among the Allied Powers of Italy, England and France, thus the infant mortality of Austria-Hungary was 22 per cent., of Germany 19 per cent., while in Italy it was 17 per cent., in England 12 per cent., and in France 10 per cent. In France infant life had been a source of particular care on account of the rapid diminution in the birth rate.

The infant mortality of this country has never been obtainable on account of the fact that in a considerable portion of the country the births are still not registered.

In New York City the infant mortality has been for three years less than 10 per cent., and this is better probably than that of any European country excepting Sweden, where the mortality is 7½ per cent. This low mortality in New York City has been attained through the efficiency of the Board of Health, the multiplication of milk depots and other agencies for the proper education of mothers in the tenements, to the gradual improvement of the milk supply, and of the hygiene and housing in the city.

Civilization, with its accompanying medical research and rapidly increasing knowledge, is producing results in the morbidity of children that could never have been expected. Thus infant mortality must have been materially diminished at the time vaccination was introduced and its accompanying elimination of smallpox from the material cause of death. In more recent years the knowledge of the causation of malaria by mosquitos has stimulated the drainage of stagnant water, which has eliminated from well administered communities, to a large extent, the deaths of infants from malaria.

Probably our most effective exhibit in the reduction of infant mortality is in the deaths from diphtheria. A death rate of 32 per 10,000 in 1894 in New York City was reduced to 3½ in 1909 and ⅛ of 1 per cent. in 1916. There is, therefore, now only one death where in 1894 there were 256.

The mortality from pneumonia is being diminished, but not by the use of specific sera, for, unfortunately, the Group 1 pneumonias which are amenable to such treatment are very rare in children. The reduction in mortality, therefore, from this disease is attributable to rational methods of treatment; the rapid emptying of the stomach and bowel contents, and the free access to fresh air. The ordinary mortality of pneumonia in children treated in hospitals is given in the textbooks as from 30 to 50 per cent. By the use of out-of-door treatment at The Roosevelt Hospital I have obtained in twenty-one successive uncomplicated hospital cases of lobar pneumonia a death rate of 4.7 per cent., and in thirty-one successive cases of uncomplicated bronchopneumonia a death rate of 3.3 per cent.

By the same method of treatment and the securing of sanitary quarters, as far as possible, the pulmonary tuberculosis death rate in New York has diminished in the past six years from 2.37 per cent. to 1.5 per cent.

The same sanitary methods have apparently influenced other diseases for which we have discovered no specific cures. Thus we find that the death rate from measles has decreased from 0.16 to 0.09 and that of scarlet fever from 0.20 to 0.02 per cent. These latter figures may be due to a milder character of the epidemics, but it seems to me probable that they are all due to better hygiene and care.

When crowding in public conveyances is forbidden by municipal ordinances; when our public schools are under more efficient medical supervision and children exposed are kept from school during the end of the period of incubation of the disease to which they have been exposed; when the benefits of fresh air are appreciated by the general public and the fact that the cold air of winter is much healthier than the warm air of summer; when peo-

*Read before the American Academy of Medicine at its 42d annual meeting in New York City, June 4, 1917.

ple stop overclothing their babies and children and stop overfeeding them with indigestible and irrational food; when the value of good health and the misery of sickness is better appreciated, our present mortality statistics in which we all now take pride will seem a disgraceful slaughter of infant and child life.

CIVILIZATION AND THE DISEASES OF ADULT LIFE.*

BY EDWARD O. OTIS, M.D.,

BOSTON.

PROFESSOR OF PULMONARY DISEASES AND CLIMATOLOGY, TUFTS COLLEGE MEDICAL SCHOOL, BOSTON; CONSULTING PHYSICIAN TO THE BOSTON DISPENSARY, TUBERCULOSIS DEPARTMENT, ETC.

Probably no two persons would give the same definition of civilization. It is "at best," as some one has said, "one of those phantom generalizations which the mind is forced to employ." One person would define it ideally as an elevation of social and individual life, a state of refinement and enlightenment; another would base his definition upon the degree of civic organization, upon the liberty, law and order under which a people live; while a third would consider the material development of a country as indicative of its stage of civilization; and a fourth would stress intellectual attainment.

Again, civilization may be viewed from the standpoint of historic age periods, as the Egyptian, Roman, Jewish, or modern civilization, that with which we have to deal in our present discussion.

That either material or intellectual development really civilizes is negatived by what is now going on before our eyes. We see a people highly developed in these two directions exhibiting in their methods of warfare almost every form of extreme barbarism. Nay! barbarism enhanced by the very "culture" they boast of.

It looks as if our ideas of civilization must be materially reconstructed if we are to permanently exist upon the face of the earth. Our modern civilization, like all that have gone before it, has apparently been weighed and found wanting, and when not engaged in destructive wars, and industrial methods which more slowly, but just as surely, lead to untimely disease and death, it seems likely to verify Kay Robinson's prophecy as regards those who remain, that they will be "toothless, bald, toeless creatures with flaccid muscles and limbs almost incapable of locomotion." Compare such a sorry product of modern civilization with an uncivilized North American Indian!

"We find ourselves to-day," says Edward Carpenter, "in the midst of a somewhat peculiar state of society, which we call civilization, but which, even to the most optimistic among us, does not seem altogether desirable. Some of us, indeed, are inclined to think that it is a kind of disease which various races of men have to pass through, as children pass through measles or whooping cough."

My especial subject deals with the effect of this kind of civilization, so-called modern civilization, upon adult life, which may be considered to be the period from eighteen to thirty-five or forty years of age. What are the diseases peculiar to this age period more or less attributable to the influences of modern social and industrial conditions?

This is an age of intense living and endeavor; an age of daring venture, of unlimited ambition for accomplishment, physical or intellectual; an age of lavish expenditure of one's forces, both by the individual and the exploiter of labor; an age when one's passions are most insistent, when social demands are great. It is the age of childbearing, with all its risks. It is the age, in brief, which thinks little of conservation of health and the avoidance of disease; an age prodigal of its forces, which seem to it to be imperishable and perennially renewed. Of course, it is hardly necessary to say that this period of life is not immune from any of the diseases which may happen to man, though, as a rule, it is exempt from those we call the degenerative diseases, which generally occur later in life.

It is the diseases or damages most commonly met with in this age period which may be fairly attributable to the evils and untoward influence of modern civilization with which my especial subject deals.

First: There are the so-called occupational diseases produced by injurious influences or poisons occurring in one's occupation, such as lead poisoning and poisoning from various gases, diseases caused by dust of various kinds, as in grinding, stonecutting, cotton and shoe manufacture, etc.; occupational neuroses from overfatigue, whatever the kind of work. It is at this age period when one is careless of his health and at his maximum strength and efficiency that these occupational diseases are most frequent, and the loss to the individual, to his family, and to the community is very great in consequence.

In recent years this subject of occupational diseases has been exhaustively studied and much has been done to obviate the avoidable risks in many occupations, both through private effort and public legislation: for example, there has lately been established at the Massachusetts General Hospital an "Industrial Clinic" with a salaried physician and secretary, which deals solely with the diseases which may be considered to have been caused by the hazards of the patient's occupation. It is obvious, however, that so long as the public demands the innumerable and varied articles which it considers necessary accompaniments of present-day civilization (from the green flowers upon a woman's hat to a finely cut tombstone) many occupations which produce these articles must, from the nature of the occupation, be conducted under unwholesome conditions. It is the price we pay for this kind of civilization. We are sacrificing to an enormous extent men and women of adult life as the result of occupational diseases.

A second disease which is more prevalent at this age period than at any other is tuberculosis. You are all familiar with the world-wide efforts now being made to control it. The majority of cases, it is now believed, receive their infection in childhood, and later if active tuberculosis occurs it is so often due to untoward conditions of living and work which arouse into activity the old latent childhood infection. In other words, it is from condi-

*Read before the American Academy of Medicine, at its 42nd Annual Meeting in New York City, June 4, 1917.

tions caused by present-day civilization that a favorable soil is prepared for the tuberculous crop. Hence the manifold efforts to procure for the wage earner better and healthier conditions of working, better housing, a living wage, the avoidance of all debilitating conditions and excesses which lower the resistance, and earlier diagnosis and treatment. What has been already accomplished in these directions is familiar to all, and the gradual diminution of the disease may be ascribed quite as much to the general improvement of health conditions as to the attempts to control the infection itself, which seems almost a hopeless task. In spite of all that has been done tuberculosis still remains one of the most prevalent diseases of this age period.

Another disease condition pre-eminently one of this period is venereal in its two manifestations of gonorrhea and syphilis. Recent investigations and statistics have demonstrated the wide prevalence of these menacing diseases, inflicting upon both the sinner and the innocent victim so much misery. Commissions in this country and abroad are active in investigating the conditions which favor its spread and in plans for its control and proper treatment. Notification, as in the case of tuberculosis, has been proposed and indeed instituted, I believe, in some communities. More and better opportunities for treatment have been afforded. Prophylactic measures have been widely taught, all indicating the desire of modern civilization to mitigate the terrible evils of this disease, while at the same time it is continually affording conditions for its incidence and spread. It is like the saloon and the dipsomanic hospital. It is the Sisyphean tragedy over again.

The sexual instinct, one of the strongest in man, cannot with safety be repressed or in so many cases be controlled either by law or religion, and hence the hope of reasonably early marriage seems to me to be the fundamental and natural remedy for the venereal evil. In the early days of our country when life was simple and one's wants comparatively few, marriage was regarded as the natural and inevitable course for young adults; Colonial history tells us that but few passed the age of 25 or 26 without being married. The young couple carried on the struggle for existence together, each making his or her contribution to the common life. Many children were born and were not considered an additional burden but a valuable asset in increasing the family possibilities of making a living. Birth control was not preached or thought of.

Now all is changed. The young man with aspirations to get on, not born with a silver spoon in his mouth, thinks he must defer marriage until he becomes established in a remunerative position or acquires property, and the young woman too often looks for a partner who can support her, not for one with whom she can cooperate in gaining a living. Hence the number of unmarried men and women or late marriages.

Not all young men are St. Anthonys and some women are of easy virtue; hence with the prospect of marriage only in the dim future the temptation to sexual lapses at the period when the sexual instinct is most insistent and persistent is very great and with some irresistible. And one of the inevitable consequences of this condition of modern civilization is venereal disease.

Many and manifold are the efforts to control it: Sex education, sex lectures to college students, moral inculcations, religion, special dispensaries and hospitals, prophylactic methods, notification and salvarsan. It is to be hoped that much will be accomplished by these various methods in reducing the prevalence of venereal diseases, but I cannot help believing that early marriage is the fundamental remedy, and this the present-day civilization, at least with the better educated class, to a large degree denies. One is reminded of the fable of the road along the edge of a cliff, over which so many fell as they rode along, that a meeting of citizens was called to raise funds for the purchase of an ambulance in which to convey the victims to the hospital. While discussing the ways and means someone mildly suggested that they put up a fence along the dangerous road and then there would be no need of an ambulance.

Second: Another evil of this age which sooner or later leads to disease is the use and abuse of alcohol. With some disease from this cause comes early, while with others the reckoning is deferred until middle life or later. Besides various definite diseased conditions induced by the constant use of alcohol, we have mental and physical deterioration, a weakening of will power, and hence a ready yielding to other injurious influences, a lowering of one's normal resistance to infectious diseases, such as pneumonia and tuberculosis. As someone has said, "Alcohol makes the bed of the consumptive." There needs no argument to show that alcohol used as it is and will be used if attainable by great numbers of average people brings evil results and disease upon themselves and harm to the community. Recent investigations have shown, for example, that instead of being a mental stimulant it is a deterrent to clear thinking. The efforts of civilization to rid itself of the alcohol evil have greatly increased in late years all over the world, as we know, and it now seems highly probable that in no distant future we shall have a "bone-dry" country as now we have not a few "bone-dry" States. The demands of the present war for physical and mental efficiency have done much toward eliminating this one of the greatest menaces to this age period.

Again, this period of adult life, as I have said, is the childbearing period, a function which, with the normal woman, is a perfectly physiological one. The conditions of modern civilization, however, have made it with the so-called higher class of women, one of such stress and strain that it has become more pathological than physiological, and many chronic conditions and often prolonged invalidism result. Indeed, confinement itself has, with not a few, become such a dreaded ordeal that twilight sleep or even cesarean section has become popular in order to escape parturition pains, which ought and could be perfectly well borne by the normal woman. With some this dread is so great that means are sought to prevent conception or render it inoperative. The so-called social demands of city life are so strenuous in present-day civilization that the woman who marries after a wearying round of such life has little vigor left for the demands of childbearing or inclination to pursue it further than the first child or two. The result is inevitable—the steady and rapid destruction of that portion

of our race which calls itself the most highly civilized. The census of the older American families shows this only too plainly. Surely no birth-control propaganda is needed for this class of women. Professor Cattell in a recent number of the *Scientific Monthly*, in an article upon the "Families of American Men of Science," tells us that a scientific man has on the average about seven-tenths of an adult son, a Harvard graduate three-fourths of a son, and a Vassar graduate one-half a daughter. If this is the result of civilization and culture, is it worth the price? If we are to eliminate poverty and disease among the poor and have "happier homes, healthier children, better men and women, a stronger nation and a nobler race," as the birth controllists tell us will result from their remedy, I believe we should seek the true remedy not in birth control, but in a living wage, a juster distribution of wealth, education, frugal habits of living, less individualism and greater community responsibility.

This is an age of intensive living. The demands of its civilization are greater than poor human nature, even in all its vigor of adult life, can satisfy without present or future damage. Indoor life, in office or factory, fierce competition in professional or business life, social exactions in city life, insufficient rest and sleep, lack of time for physical exercise and mental diversion, monotonous work which makes of millions beasts of burden—these and many other abnormal influences make such strenuous demands upon one's vital energy that many fall by the way before middle life is reached or enter it permanently disabled. How many young old men we now see!

There is also the class of the idle rich and those who have no steady occupation or definite aim in life, who are an excrescence of modern civilization and who are ready victims of many evil conditions or disease engendered by their mode of life. This seems to be particularly true with women of this class at this age period, and hence the common disease or condition we call neurasthenia, a pathetic state, rendering its victims miserable in body and mind and making havoc with the equanimity of the family.

Finally: Although modern civilization, as we have seen, has much to answer for in the evils and diseases it inflicts upon adult life, it also has much to its credit. Not many years ago typhoid fever, for example, would have held a prominent place in the diseases of adult life. Now, however, it is almost negligible in comparison with its former prevalence, thanks to a more rigid milk inspection, a pure water supply, better sanitation and antityphoid vaccination. Diphtheria, again, has lost its terror through its antitoxin, and surgery is now preserving many adult lives from an untimely death from appendicitis, and so with many other formerly prevalent diseases.

Three years ago we were congratulating ourselves upon these and many other advances in the prevention of disease, and upon the general progress in social uplift. The average life limit was increasing. Our International Scientific Congresses seemed to strengthen the ties of universal brotherhood. We were all engaged in the peaceful and beneficent work of eliminating the evils of modern civilization and developing a vigorous adult life. We contemplated with satisfaction the high achievement of laborious centuries in the prevention of disease, and we thought we saw the distant gleam of that day which the great prophet predicted in his beautiful imagery when "the wolf also shall dwell with the lamb, and the leopard shall lie down with the kid and the calf and young lion and fatling together; and a little child shall lead them." Then suddenly the thin wall of civilization seemed to burst asunder and let loose the immeasurable fury of a brutality masqueraded in the garb of culture. And now it seems almost farcical to be discussing the diseases and danger of adult life when it is being wantonly destroyed faster and more cruelly than was human life by the Great Plague of the Middle Ages.

When one considers this vast cataclysmic collapse of our modern civilization with the loss of so much which had been achieved through long years of painful effort and the best of young manhood daily sacrificed in hecatombs, he is inclined to agreed with Edward Carpenter that "civilization is but a disease whose cure we still have to seek"; or with Dr. Eastman, of Indian birth, whose experience covers the whole range of civilization, that "behind the material and intellectual splendor of our civilization, primitive savagery and cruelty and lust hold sway undiminished."

381 Beacon Street.

CIVILIZATION AND THE DISEASES OF MIDDLE LIFE.*

By HARLOW BROOKS, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE, NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; VISITING PHYSICIAN TO THE CITY AND MONTEFIORE HOSPITALS.

It is a little difficult at this particular time to define just what one is to understand by the term Civilization and in a way many of us feel that the use of the word now obligates some sort of an apology. however taken in its relation to disease, this frank admission of shaken faith seems to obviate the customary explanation. Not in this relation alone, but in many others also, it seems as though the methods and life of those whom in the past we have chosen to call uncivilized have certain advantages. This is especially evident since the brutalities and bestialities of man of today exceed those of the so-called uncivilized man, or, as Mark Twain has so caustically pointed out in his posthumous work, excel even those of the beasts. There appears no longer necessity for the open question of whether in many ways we have not deteriorated rather than improved as we have gone on in our supposed evolution.

Hrdlicka has shown that at least among the Southwestern tribes of the Red Indians, longevity and health are much more commonplace than among ourselves, and La Fleische the Omaha has well remarked that in his recent struggle for health the white man has been forced to learn the customs and imitate the life of the red man, who in turn has been forced by legislation and by religion to abandon the very habits which gave him health, longevity,

*Read before the American Academy of Medicine, at its 42nd Annual Meeting in New York City, June 4, 1917.

and morality and which some of us are now wisely learning to imitate.

Middle life may be looked upon as the proving period from a health standpoint of the soundness or otherwise of the methods of the earlier life. In youth and early adolescence, inherent, congenital health and stamina may carry through existence and tolerable activity; in old age deterioration and abatement of physical and mental force are as natural as are the habits of infancy. It is then in middle life, when the quality and quantity of productiveness should be at their maximum, that our truest test of life methods appears. There be indeed few who, as Stradivarius at 93, can still produce the acme of art and soul, and it is the middle period only which gives forth the matured and characteristic of most lives. It then is the time of life for which all anterior periods are preparatory and which should be succeeded by the time of reward and laurels—old age.

It behooves us then to consider particularly the effects of civilization on middle life, and especially in its relation to disease, since this is the period when a man should be of greatest economic and spiritual use to his country and to his kind. Conditions which, no matter how beneficial they may be to early adult life, hamper the middle period, are harmful in those most fruitful years when judgment and experience should be still combined with force and virility.

Civilization has in its development evolved specialization. A man is no longer his own farmer, musician, plumber, and preacher. Success in the material world has obligated a specialized life. The successful physician or scientist has no longer time to do the physical things of his life, to work in his own garden, make his own apparatus, to care for his horse, or even to change his own tires. Those in mental occupations have now become largely unable to attend to even their personal physical demands; the sedentary brain worker has become constipated and the physical worker in his middle age has become a deteriorating mass of bone and muscle, often activated by only selfish, jealous, and unpatriotic motives, dominated mentally perhaps by the demagogue or parlor anarchist.

Probably in no other field of medicine has the penalty of civilization exacted a longer or more severe penalty on middle age than in the realm of cardiovascular disease. Arteriosclerosis, other than the naturally senile type, even today, among those tribes of men living under relatively selected conditions, is rare. Study of the diseases of primitive man, at least in this country, has shown that cardiac or vascular death was infrequent and even the most intelligent tribes had but little knowledge of diseases of this character. Early mental deterioration and insanity were so unusual among the Indians that persons afflicted with these calamities were and are looked upon as special and unusual manifestations of the divine wrath. They are the commonplaces of our time and kind. Undoubtedly cardiovascular disease together with its closely associated renal disturbances has greatly increased as the customs of civilization have developed and these are the dominant disease conditions of present day middle life.

In so short a time as is allotted to the consideration of this subject today it is of course impossible to enter intimately into the discussion of the why and wherefore of this acknowledged fact, but in brief it may be considered as mostly due to the conditions of mental worry and strain, with their consequent elevation of blood pressure which the conditions of modern life impose. Lack of balanced or correlated physical exercise is also an undoubted factor in this relation, for it is very doubtful if, when the results of dissipation are eliminated, hypertensive conditions develop in lives typified chiefly by physical output.

Insufficient and irregular sleep are also undoubted factors of great importance in the evolution of those disease conditions which develop peculiarly in middle life. It is more probable that it is the insufficiency rather than the irregularity of the sleep which is chiefly responsible, for the hunter or warrior seem to have suffered but little from irregular rest, which was as insistent a factor in his life as the attending of medical societies is in ours.

We have probably generally underestimated the importance of recreation in the prevention of the hypertensive and degenerative disturbances of the vascular and renal system in middle life. Unfortunately with us most of those engaged in lives of great mental activity also take their pleasures in a mental way, they study or read perhaps other subjects, but always with the same type and direction of energy dispersion, using even in rest the same overworked mechanism. True, many of us are learning to imitate the red man and go to the hills and streams for our pleasures, and the hill man comes to our cities to hear our music and to read our books and to go to our colleges, while we go to sit at the camp fire of this or that man who lives close to nature. Burroughs, Thoreau, Jim Simpson, and Tom Buffalo teach and treat us.

Another type of disease which also becomes a very serious element in middle life and which also seems to be dependent for its predisposing essentials in great measure on the customs of civilization embraces the disturbances of the respiratory tract. The chronic catarrhal conditions of the cities and of the dusty occupations, the emphysema of the gouty and the subject of the occupational disease first become of serious import during middle age. The tuberculosis contracted in the class room or the sweatshop or in the compact community of the prison, may not become seriously disqualifying until this age. These are of course typically the diseases of civilization, conditions which history shows us beyond doubt were infrequent, almost unknown in primitive man. Anthropological authority states that with the primitive Americans these diseases were unknown. However, following the observation first made by Darwin (Voyage of the Beagle), that when any infection is introduced to a primitive and utterly unaccustomed people it rages for a time with terrific vigor, tuberculosis has raged among the reservation Indians and syphilis among the Christianized islanders of the Pacific. It is interesting to note that for our really basic principles of treatment of these conditions we have mostly reverted to the life environment of that man who, in our superiority of civilization, indexed by the Zeppelin and U boat, we have called the savage.

Pneumonia, which assumes its most serious and

grave aspects in middle or late life, is a disease of civilization. We are lately almost of the opinion that this disease, which always has been one of communities, is a transmissible infection or perhaps contagion. In our prophylaxis, and even in our more sensible hygienic treatment, by the open air method, we have reverted again to the habits of our red progenitors.

The numerous disorders of digestion usually become most annoying, if not most insistent, during the period allotted to me. The man who hitherto has been able to go to public dinners indiscriminately, who has overnourished himself with rich and unnecessary foods, now becomes interested in diets, in calories, in pepsin and the antacids, and in various food fads that he may undo the harm which the dietetic customs or temptations of civilization have offered him. When one enters closely into the analysis of most of these cases of dietetic disturbances, one finds that the elemental flaw is in the taking of too rich a diet, if not as a whole in actual calories, then in certain parts of the diet and notably in the nitrogen elements. It is of course foolish to think that any one diet can be fitted to all classes of men—for instance, that the food of a soldier or sailor is that suitable for the student or artist. The food must be adapted to the energy needs, to the habits, habitat, and occupation of the patient. In civilized youth and early adult life the taste of the patient together with his opportunities chiefly determine; in savagery it is necessity and obligation. But in middle life a more careful study is demanded, and, say what we will, it becomes in the end a study in individualism, since neither two persons nor two horses demand the very same diet in quality or quantity.

It most cases where dietetic changes for one or another reason are difficult or impossible, the same result may often be encompassed by changes in the other factors of life. The sedentary man finds that he can comfortably take an ordinary diet when he favors combustion by adequate and suitable physical effort. The trainer or soldier of middle life finds that he can manage his customary diet by more physical inactivity, by a short period of rest after eating, as the sensible animals do, or by a more sensible spacing of his meals.

Middle life is notably the period in which the diseases of metabolism become most manifest. It is then that diabetes becomes most frequent in occurrence, though of course by no means so serious in its fatalities as when it develops in earlier life. Let us see to what extent the habits of civilization contribute to the disorders of this character, obesity, hyperacidity, and the large group of hepatic disorders. Nearly all these conditions entail, as a primary essential in their treatment, two factors—change or elimination in diet, increase or alteration in exercise. In nearly every concrete instance even you will note that the alteration is in a direction harking back nearer to the custom of our ancestors. The native who secured his sugar mixed with much cellulose or other form of vegetable pulp, as from cane or from the sap of maple or box elder or from the juice of natural fruits, suffered little from strain of his sugar tolerance and the man whose meat supply was contingent on a climb to the haunts of the big horn or a brisk gallop on an unsaddled pony in the buffalo drive, did not contract gout. The tribes whose starchy foods must be carefully and laboriously collected from the fields of wild rice or painfully nurtured in a Hopi cornfield and stored up for the winter or those whose fats were won with bow and arrow, have not suffered from hyperacidity. The Esquimo, who must struggle and scrimp for every ounce of his essential fat, has not required the service of Oertel or von Noorden. All the diseases in this protean class are essentially the result of the customs which civilization compels or invites. Their cure lies in practically a reversion to the conditions of uncivilization as we still speak of it.

Middle age is the period of carcinoma. It is of course most difficult to judge statistically of a subject so dependent for accurate diagnosis on methods which involve to so high a degree the detail of modern science. However, if we may be permitted to judge from the general lack of study and description of the neoplasms by the ancients, we must conclude either that the conditions were rare in olden times, certainly more so than now, or that the scientists and physicians of that date failed to observe them. This would seem unlikely when we consider the accuracy and astuteness with which many other disease conditions were described by our medical ancestors.

Study of wild animals born and bred under natural environments indicates the exceeding rarity of neoplasms among them as compared to impure species or those which have undergone at least semidomestication, as has the dog, the horse, the white rat and mouse, or our pet birds, especially canaries and parrots among which neoplasms are frequent. It is the universal remark of those who have lived with, or extensively studied the primitive and pure races that neoplasms are but little known among them, notably so if we exclude the granulomata. It is, of course, altogether too sweeping a statement for so few premises to conclude that therefore civilization is a potent factor in the evolution of neoplasms, but it certainly is a fact that uncivilization is exceedingly infrequently associated with new growths.

As a clinician I should not think my time well spent in such a study as this did I not feel that it presented much which can be well utilized in the prevention or mitigation of disease and as a contribution to happiness and to the real welfare of man. I bespeak a return in many ways to uncivilization so that we of middle life may live long in the land which the Lord our God giveth us. Incidentally that we may turn out as much or even more work of higher and more original character.

The keynote is in the living of better balanced and less specialized lives. The artist must again be in part artisan, the thinker also workman. Few sculptors now actually hew and chisel their marble; that is done by workmen; yet Michael Angelo, soldier, musician, engineer, sculptor, and painter, shaped his own immortals and is still rated as a good artist. We have delicate machinery and perfected tools, beside the crude implements of Amati and Gunarius; we think that the science of acoustics is comprehended by us, and yet the vibrations of the souls which the artisan Stradivarius shaped in his fiddles still thrill the world, and he and his Cremonese colleagues have no equals.

Years ago, when Columbus was a puling infant, the Duke of York, said to be the same kindly and quite modern gentleman who preceded the army of the King with the head of his uncle on a pike, wrote a description of rabies which, aside from the vaccination treatment, has left little for civilized science to discover or originally describe. (The Master of Game).

But we of civilization are learning. I doubt if there be a really good trout stream in America which is not known to some clergyman, doctor, or professor. A great surgeon has become a nut culturist. The banker and broker have their weekly day on the golf course. We are studying our diet and our exercise, we are finding that the greatest in any art, craft, or science is often achieved by a balanced life, of mingled physical and mental effort, by a sparing and individually studied diet, that is by a busy life, seamed and savored with a vein of diversion and relaxation, which are as essential to a healthy and productive middle age as are salt and water to our diet. When we have fully comprehended that much of civilization is disorganizing and much of savagery elevating and healthful, we shall have prolonged middle life and freed it in large part of many of its most serious disease conditions. We shall have also extended and improved our usefulness and originality.

5 West Ninth Street.

THE EARLY DIAGNOSIS OF TUBERCULOSIS.

By MARY E. LAPHAM, M.D.,

HIGHLANDS, N. C.

PHYSICIAN TO HIGHLANDS CAMP SANATORIUM.

Tuberculous processes in the lungs may be classified according to their location and nature into two main types: those chiefly developing upon the inner surface of the air passages and those extending along the bronchial sheaths and not entering the air passages. A combination of the two forms the mixed types.

Tuberculous processes developing upon the secretory surfaces of the air passages attack the functional tissues of the lungs and are called parenchymatous; those extending along the sheaths of the bronchi and not attacking the functional tissues of the lung are called interstitial.

Parenchymatous tuberculosis resembles catarrhal pneumonias: there is an inflammatory reaction resulting in hyperemia, transudation, exudation, proliferation, desquamation, increased secretory activity and the accumulation of the products of inflammation. The cellular proliferation, the accumulation of cellular débris, fluids, mucus and pus gives more or less density to the tissues which is manifested physically by tactile and vocal fremitus and dullness; the inflamed surfaces of the air passages and pressure from the surrounding infiltrations exaggerate and roughen the breath sounds: Necrosis, caseation, mucus, etc., cause the appearance of râles. The decomposing tissues and tubercle bacilli liberate toxins which destroy the ability to assimilate food and the desire for it so that there is a loss of appetite, weight, and strength. The irritated tissues demand the removal of pus and mucus by coughing: vasomotor relaxation is expressed by dyspnea on exertion: increased temperature and a rapid pulse show the toxemia, etc.

The characteristic feature of parenchymatous tuberculosis is the broncholobular pneumonic reaction caused by the presence of tubercle bacilli upon the secretory surfaces of the air passages. Unless the site of attack is too deeply covered by a cortical layer of normal tissues, these pneumonic densities are betrayed by physical signs. Their nature produces physical signs and symptoms.

Interstitial tuberculosis is exactly the opposite. There is no attack, no defense, and no inflammatory reaction. Just as connective tissue infiltrations creep through the liver, spleen, kidneys, and pancreas and cause the atrophic, cirrhotic liver, the granular, contracted kidney and the sclerosed spleen and pancreas so does this interstitial sclerosis of the lung gradually obliterate one functional lobule after another until finally fibroid phthisis results. The interstitial infiltrations of these organs are all analogous with each other and all characterized by the subtle extinction of functional capacity, and a prolonged course which is not associated in the earlier stages with physical signs or symptoms. The absence of inflammatory reaction corresponds to the absence of diagnostic data, but this absence never proves that there is and can be no danger in the future from these tuberculous infiltrations.

Fibroid induration of the lung—or interstitial sclerosis—begins at the hilum probably as extensions of tuberculous processes from the bronchial glands; whether the bacilli are carried along by the back wash of sluggish stasis in the circulation surrounding the hilum, or whether they advance point by point by direct contiguity does not greatly matter. The important feature of these infiltrations is that they are not processes of inflammation but of organization. They are connective tissue reactions outside of the parenchyma. These sneaking, creeping infiltrations thread their way through the lungs—without doing any great harm—until they advance along the walls of air passages unable to withstand their contracting influence so that their lumen is narrowed, when the air passes through less freely and the weight of the atmosphere is not well transmitted. Often the air passes on to the terminal lobuli more freely than it can return, because the stenosis is relieved by inspiration and enforced by expiration. The insufficient entrance of air causes a reduction in the force of the breath sounds, the tardy return of the air causes prolonged expiration. The degree of constriction not being the same through all the smaller air passages, the degree of stenosis varies and with it the ability of the inspired air to distend the lobuli with equal force and promptness. Instead of the uniform prompt unfolding of all the lobuli, one after another expand often with creaking and grumbling, so that the unequal entrance of air causes interrupted breath sounds, or cog-wheel breathing. As the stenosis increases, the terminal areas supplied by the obstructed air passages collapse and form areas of atelectasis which furnish tactile fremitus, but not dullness, which is one of the last signs to appear. These atelectatic areas are not inflated by inspiration and the intercostal spaces

covering them remain depressed as the air passages become stiffened and thickened by the scaly barnacles covering them. They lose their ability to stretch as the chest wall is pulled out and the intercostal spaces lag in inspiration. As the stiffness begins in the hilum there is often dimpling over the roots of the lung, until even the ribs are held back and flattened-lagging areas are seen. The lumina of the larger air passages are not compressed—they remain open and their air content, instead of being diminished, is often increased by the delayed expiration and lack of the normal force of collapse of the terminal areas to drive the imprisoned air out against the weight of the atmosphere. There may be, therefore, no dullness but rather better resonance than normal, even over flattened lagging areas.

In our experience we have found that these connective tissue infiltrations are most apt to follow the main bronchi up from the hilum through the paravertebral or parasternal regions on into the apex. The first physical sign obtained is increased tactile fremitus in these regions. Then suppressed uneven interrupted breath sounds and prolonged expiration-areas of lagging and flattening are characteristically seen between the second rib and the clavicle, dullness is sooner and more often found over the hilum and paravertebral or parasternal regions—the supraclavicular regions have not been affected as soon in our cases. D'Espine's sign has almost always been present.

The final danger from sclerosis of the lungs is loss of breathing power, but this is too remote to be often reached as a typical result. Before the sclerosis completely strips the bronchial branches of their breathing spaces, necrosis, or perforation of an air passage or rupture of blood vessels changes the purely fibroid into fibro-caseous or caseous-fibroid and parenchymatous types with their physical signs and symptoms.

From the beginning of extension of tuberculous processes from the bronchial glands into the lungs to their logical termination in fibroid phthisis, or in parenchymatous pneumonias, their progress is complicated and uncertain. They may persist throughout life with little or no impairment of health, and good working capacity, or they may rapidly cause death by hemorrhage, acute miliary tuberculosis, the typhobacillemia of Landouzy, or caseous pneumonias. In their purity, sclerosing infiltrations are of indefinite duration, and, as a rule, they do not affect the health specifically as the parenchymatous inflammations do, so that they are apt to be overlooked until complications develop or until a sufficient advanced stage is reached. Until this happens these tuberculous processes remain clinically inactive and constitute the great world of concealed tuberculosis, which we are just beginning to explore. Latent or concealed or clinically inactive tuberculosis represents that period of development of sclerosis of the lungs which has not created symptoms associated with the diagnosis of tuberculosis. When we discover physical signs in the lungs, showing beyond question that they are of a tuberculous nature, we say that the case is of no importance clinically unless we recognize the bad effects of tuberculosis by cough, pulse, temperature, loss of appetite, weight and strength, etc., etc. When we dip down into the sea of clinically inactive or concealed cases of tuberculosis and fish up a case with physical signs, but no symptoms indicating any bad effects, we say that it requires no treatment, is of no clinical importance and drop it back again among the other concealed cases just as we would drop back a fish not large enough to fry. The questionable point in this procedure should be whether it is better to dismiss or retain such a case under observation. We know of any number of such cases with excellent working capacity often hampered somewhat by lack of strength, but by no means justifying a tuberculous regime. If we should withdraw every case of tuberculous sclerosis of the lungs from active pursuits what an extraordinary accumulation would result. All professions, all ranks, all classes would be represented. With sufficient training the detection of sclerosis of the lung becomes so easy and the number of cases so great that it is not the difficulty of finding them but their classification after they are found which staggers us. We must avoid ruining a man's activities, but we must also remember that every case of manifest tuberculosis passes through this prodromal stage. We are fully informed of the universality of tuberculous infections of our people. Are we equally well informed concerning the frequency with which this infection results in sclerosis of the lungs? And do we know anything definite concerning its ultimate outcome? Virchow said that at some time or other we all develop tuberculous processes to a greater or less extent. Behring said that the first verse of the funeral chant heard over the grave of a victim of tuberculosis was sung over the cradle of a newborn babe. Phillippi says that the first act of the tragedy of tuberculosis of the lungs is played in the bronchial glands of infants. Naegeli showed that 90 per cent. of all autopsies had more or less pronounced traces of tuberculosis. Hamburger and many others have taught us that an exceedingly high percentage of tuberculin tests are positive. We know that nothing is more common than infection by tubercle bacilli and its consequent termination in tuberculous processes in the bronchial glands and lungs. What we do not know is to what extent these infiltrations are permeating our people. We are told that the proportion of manifest to concealed cases of tuberculosis is as one to eight, but this is merely guess work. We can have no positive knowledge until all our people are examined and reported. Until then we cannot know anything about this world of concealed tuberculosis in which now and then a manifest case is discovered, fished out and put under treatment. During all the periods of delayed manifestations we say that the case is not important clinically. As long as Humpty Dumpty sits on the wall we let him alone, but when Humpty Dumpty has a great fall we do our best to accomplish what all the King's horses and all the King's men could not do. It seems very probable that the future prevention of tuberculosis may consist more in trying to prevent clinically inactive cases from being transformed into manifest ones, than in gathering up the fragments of what should

never have been broken. Less patchwork, less palliation and infinitely more prevention is what we need to keep occult from becoming evident tuberculosis.

We must begin further back and lock the barn door before good health is stolen away from us. How shall we begin this work? To properly work we must first be taught. We need enough research work to establish the necessary foundation for our belief that the new-born babe enters the world of concealed tuberculosis very soon after its birth for the reason that coincidently with other development tuberculous processes begin; that latent, concealed, clinically inactive tuberculosis is prevalent throughout infancy and childhood as well as later life; that this class of concealed cases is characterized by the extension of tuberculous processes through the lungs which do not create the physical signs or symptoms we are accustomed to depend upon for the diagnosis of tuberculosis; that a certain small percentage of these cases become manifest during infancy, early childhood, young manhood, and later on in life, but that the greater number permeate our people without ever being recognized.

In cases of physical signs of tuberculosis of the lungs without symptoms we should know all that the gradual obliteration of the lungs by interstitial sclerosis can accomplish in impairing health. Just because the symptom complex we are accustomed to rely upon does not appear does not justify us in saying that there is no danger. We must remember that all cases of manifest and fatal tuberculosis pass through this period and also that it is quite possible that there are other symptoms equally reliable which were not handed down to us by Hippocrates. If we are to depend upon symptoms, we should know all that can be known concerning them because our sanatoriums are filled, not with victims of tuberculosis, but with victims of ignorance, of lack of knowledge, of mistakes, of blunders, of criminal inability to recognize symptoms offering abundant testimony.

The classifications of these symptoms must include all those caused by all kinds of tuberculous processes in the bronchial glands and lungs because there is no way of knowing whether any symptom is caused by one or the other. We cannot tell whether a cough is caused by pressure from enlarged glands or pneumonic consolidations or adhesions. Systemic injuries caused by tuberculous processes without regard to their location furnish a comprehensive classification and a good working basis for the early diagnosis of glandular and pulmonary tuberculosis which, as a rule, are synonymous with each other.

Combé, Gagnoni, and others think that the first influence of tuberculous toxins is felt in the vasomotor system and is manifested by a fall in blood pressure. The relaxation of vascular walls may be shown in the skin by erythemas, tinea versicolor, erythemia nodosum, acneform eruptions, tuberculides, eczemas, etc. In our histories we find that the exudative diathesis has very frequently preceded the manifestation of tuberculosis and this, together with the beneficial influence of a mountain climate, has led to the belief that it is a form of tuberculous vasomotor insufficiency. Cyanosis of the lips and finger nails is said to be another form of vasomotor dilatations and it is interesting to observe that all these relaxations are aggravated by alcohol and benefited by adrenalin. The same is true of cold, clammy hands and feet, even chilblains, and tendency to sweat which suggests that they are possibly due to lack of sympathetic stimuli. Josue describes four cases of tuberculosis with death from adrenal asystole caused by exhaustion of the adrenals. Heisler reports a case of cardiac insufficiency treated for heart failure which was due to tuberculosis of the bronchial glands without a single symptom suggesting tuberculosis. Pollak thinks that sluggish circulation in the skin underlies the increased growth of lanugo, especially over the temples, the chin, and between the shoulder blades, and the long silky curling eyelashes so often seen in tuberculous children. It is possible that many cases of thick, blotchy complexion with eruptions suggesting syphilis, are really tuberculides of the face and that the acne-like eruptions so often seen on the back and chest are not always caused by indigestion and may be tuberculides also.

As a consequence of vasomotor insufficiency, the circulation in the hematopoietic and gastreintestinal systems is said to become relaxed with consequent stasis, hyperemia, and disturbance of function. In the hematopoietic system the most common disturbances are chlorosis and anemia The chlorotic patient has the same cardiovascular and gastrointestinal and menstrual disturbances with the same depression of the nervous system as the tuberculous patient. One so often represents the other and their frequency is so great, that it seems reasonable to demand the exclusion of tuberculosis in all chlorotic cases.

The anemia is simple or approaches pernicious anemia with the same blood picture of large, dark, oval red blood cells, increased color index, poikilocytosis, etc. Although there have been many descriptions of the blood picture in tuberculosis, we have found it more a matter of personal condition of the patient than an indication of tuberculosis. Secondary infections, empyemas, etc., may give a nuetrophilic count of over 12,000. In some cases there is, even in children, an almost complete absence of lymphocytes; in others they are increased. In cases with almost no leucocytes save the large mononuclears of the myeloblastic series, an exhaustion of the bone marrow has been inferred comparable to the appearance of nucleated red blood cells. In some of our cases we have found a remarkable activity in platelets characterized by their grouping together into rosettes like trypanosomes and showing two distinct types of growth: an elongated form looking something like an attenuated trichomonad and circular forms varying in size and density of staining. The monad forms sometimes suggest a further development like a flagellate like organism sometimes pointed into red blood cells as if about to enter them.

The gastrointestinal disturbances begin even in earliest infancy and are characterized by typical disorders of function seen in gastrointestinal diseases proper or by a highly negative condition leading to atrophy. Infants with positive tuberculin

reactions may continue to gain in weight for an indefinite period and to maintain the appearance of perfect health. The first sign that the infant is not withstanding the toxins of its tubercle bacilli is failure to gain the proper amount of weight. At first this failure is not regarded as important, but thought to be simply accidental until as the months go by loss of weight appears and the babe is seen to be losing in every way. Eventually marasmus results in a typical picture described by Pollak as the tuberculous habitus. Aronade comments on the unsuspected frequency of tuberculous lesions in these atrophic infants. It is probable that many cases of gastrointestinal disturbances are treated upon the basis of functional or structural disorders when they are really symptomatic manifestations of tuberculous toxins. In these masked cases there are two extremes of depression and stimulation of functional activities. In the depressed type the babe does not want to eat, leaves its bottle unfinished and turns away from it with a fretful cry. Older children have to be coaxed to eat and if left alone until they are hungry, the longer they go without food the less they care for it. The secretory activity of the gastrointestinal tract seems to be paralyzed and peristalsis is so inefficient that obstinate constipation results. The abdomen is distended, there is a good deal of trouble with gas, and many of these older patients find their way to specialists for the treatment of dyspepsia. In cases of over-stimulation there is over-secretion with hyperacidity, gastralgias, enteralgias, pain in the right hypochondrium, and region of the appendix. Pain in the epigastrium may be severe enough to simulate gastric ulcer or even the gastric crisis of tabes. In erosion of the esophagus, pressure upon the branches of the vagus has caused the typical picture of gastric ulcer before any sensations of discomfort were felt in the throat. In infants and young children, hyperacidity, diarrheas, gastric distress, nausea, etc., are especially apt to become conspicuous after an acute infection, measles, grippe, etc., or even after a bad cold. Sometimes an exceedingly acid condition develops with inability to assimilate food although the appetite is ravenous and immense quantities are eaten. Since all types of indigestion and dyspepsias and functional disorders of the gastrointestinal tract are induced by tuberculous toxins in infants, children and adults, would it seem unreasonable to exclude a tuberculous foundation?

In the nervous symptom fatigue, loss of strength and inability to produce sufficient energy may be the most marked symptom of tuberculosis. The neurasthenia of hysteria is often laughed at and the patient is told that he is "hipped" or else overworked and needs a little vacation. The infant is listless and depressed; the child wants to keep quiet, does not want to play, and avoids physical efforts as much as it can. This is not always due to lack of energy or ambition, but rather to an instinctive sense of self-protection. The child knows that if it gets tired it will feel badly. Its legs and back and head will ache, it will lose what little appetite it has and feel weak and sick all over. As a rule the child does not explain why it does not want to do things, but when urged to get out to play it evades and remains as inactive as possible. On the other hand, a boy may realize that he is not as strong as his mates, so he takes all the exercise he can get hoping to get stronger and stronger by so doing. He tries to train himself, but instead of getting stronger he feels badly, does not want to get up in the morning, loses his appetite, feels that he is too tired to eat. He sleeps badly, is cross and fretful. After a few days' rest he recovers appetite and good spirits and is himself again. Such a boy often shows rather extensive infiltrations, which makes watchful care highly desirable. Often the heart is stretched and resembles the stretched heart of an athlete.

In the autonomous systems the effects of pressure and toxemia upon the vagus and sympathetic are confused. Some of the pressure effects are well defined as when the fibres of the vagus are compressed in erosion of the esophagus by enlarged tuberculous glands, when there is pain in the larynx amounting even to laryngospasm and marked changes in the quality of the voice, with no changes in the larynx. In these cases the first sign of tuberculosis has been pain in the epigastrium and the clinical picture of gastric ulcers. Lucas reports a case of the removal of a normal appendix for pain caused by tuberculous processes in the bronchial glands. Tabetic changes in the nerve roots in cases of chronic tuberculous meningitis have caused girdle pains and typical gastric crises, together with pain in the abdomen. Are the sensations of abdominal pain coming on before pneumonias due to pressure of the pneumonic infiltrations upon intrathoratic nerves? If so, may abdominal pains be considered as symtomatic of pressure upon the phrenic and vagus nerves by tuberculous or other infiltrations? May the same be said for the pains in the cervical region, the spine and the muscles supplied by the branches of the last four cervical nerves? Pain in the trapezius is a classical symptom of very frequent occurrence and often pain in the epigastrium, especially on a line connecting the tenth ribs, is equally significant. Tracing out the branches of the phrenic and vagus nerves, we find that pain in their terminal areas is very common in tuberculosis. Irritation of the phrenic nerve may be demonstrated by pressure along its course, and the descriptions of sub-diaphragmatic pleurisy suggests that its clinical picture based upon irritation of the nerve endings in the diaphragm may be paralleled by irritation of the nerve trunks. If so, then pain in the terminal areas of the phrenic, whether upon the under surface of the diaphragm or in the cervical region, or down the arm, or even many of the pains commonly regarded as pleuitic, might represent a neuritis of the phrenic nerve. We have had cases of supposed pleurisy coming to us in which the pain accurately followed the insertion of the diaphragm from the sternum to the spine and others with the pain running up towards the axilla so severe as to demand narcotics for weeks, in which the pain entirely disappeared and the temperature also after adrenalin was given. We are beginning to consider many pleurilic pains as really a manifestation in terminal endings of a neuritis rather than inflammatory processes on the pleural surfaces.

In the history of tuberculous patients, chorea and spasmophilia occur so frequently that a cause of relationship is suggested by the influence of tuberculous toxins upon the vagus. Sufficient research might show that vagotonie and sympathicotonie

were induced for the same reason. In the same way, herpes zoster and angioneurotic edemas are so often associated with tuberculous conditions that, like the exudative diatheses, the relationship seems more than accidental. All these allied conditions occur so frequently in the histories and in manifest cases, that we have come to regard them as manifestations of the influence of tuberculous toxins upon nerve trunks. As a rule they are intractable to treatment and we have had better results with adrenalin than any other method, which suggests that these edemas may be associated with vasomotor instability and depression of the sympathetic system.

We see other sympathetic disturbances manifested by the unequal pupils, the flushed cheek, the protruding eyeball, exophthalmos, the rapid pulse, the depressed type of gastrointestinal disturbances, etc. Gagnoni believes that the sympathetic may be more or less unequally affected in three segments: the cervical, the solar plexus, and the pelvic. Can it be that sympathetic changes influence the development and functions of the ovaries and uterus? Can that be why we so often find infantile genitalia and menstrual disturbances in tuberculosis? Certain it is that nothing is more common or marked than menstrual irregularities. Menstruation is hard to estabish—is apt to be delayed—or too soon—too scanty or too profuse. It may be so painful as to demand operative interference, but its chief characteristic is its undue influence upon constitutional irregularities as well as upon the specific manifestations of tuberculosis. Any disordered function may be aggravated by menstruation. The neurasthenia, lack of appetite, loss of weight, nausea, spitting up of food is increased, and when menstruation is skipped the patient does not feel as well until it reappears at the proper time. The cough is worse or only appears at this time. The pain, stiff neck, headache, sense of pain, weight and depression through the upper part of the lung and the physical signs of tuberculosis are all increased. Hemorrhages, often only slight, are especially symptomatic and when no physical signs are found they are apt to be disregarded until the increasing severity arouses suspicion. In the menstrual disturbances of young girls a local examination may not be as instructive as the exclusion of tuberculosis and operative interference not as beneficial as tuberculin.

When enlarged bronchial glands compress the superior vena cava or even obliterate it the return of the blood to the heart is interfered with so that the veins of the face are distended, especially those of the nose, and there are edemas and cyanosis of the eyelids and conjunctival sacs, cyanosis of the lips and finger nails, unilateral distensions of the veins of the neck, especially prominent after exercise, a venous network across the upper surface of the chest and abdomen, dyspnea, etc. Such a condition has developed for years with death at sixty-four without ever having occasioned any suspicion or recognition of its tuberculous nature. Another case, with supposed death from pneumonia, would never have been understood without the autopsy. We have had cases of transient edematous swelling of the conjunctival sacs and side of the nose, brought on by overexercise and overheating, and one of these cases usually had an attack of furunculosis after such edemas. In another case the pressure was so increased by overexercising that the blood was held back in the neck almost like an aneurysm.

Pressure on the trachea and bronchi causes coughing, usually explosive, paroxysmal, high pitched and so closely resembling whooping cough that a diagnosis is difficult, especially when vomiting follows the coughing. Under three years of age, this paroxysmal coughing with expiratory dyspnea and râles means tracheobronchial stenosis, which is apt to terminate fatally. After this age the stenosis becomes chronic and may cause periodical attacks of asthma aggravated by the approach of menstruation or overexercise or acute infections or any factor increasing the hyperemia of the enlarged glands. The degree of enlargement is not constant, so that the pressure varies and the attacks come and go at greater or less intervals.

The paroxysmal coughing or sudden extreme dyspnea may herald perforation and obstruction of the trachea or main bronchi by caseating glands and death follow rapidly. These cases coming on suddenly in robust children are usually mistaken for croup or diphtheria. In other cases fever, nausea, vomiting, cyanosis, unconsciousness, and death resemble tuberculous meningitis. The presence of tuberculous processes is seldom suspected in these well children, but a few diagnoses have been made in time and the dangerous glands removed. If all cases of sudden death from croup or suffocation could be autopsied it would help us in our knowledge of tuberculosis. Further consequences of tracheobronchial stenosis are bronchitis, asthma, emphysema, atelectasis, and bronchiectasis. Pain anywhere in the chest may be caused by pressure, but it is especially significant over the root of the lung posteriorly, where it may be so aggravated by bending over, as in writing or sewing, as to become intolerable. The interscapular region may be especially sensitive to cold, and the patient knows well that chilling between shoulder blades means a bad attack of bronchitis. A tendency to colds, to bronchitis, to pneumonia, etc., may betray an unusually sensitive condition of mucous membranes which is highly characteristic of the effects of tuberculous toxins. In these cases overexercise or too much strain of any kind may mean a bad cold or even bronchitis. We have repeatedly seen "colds" and "bronchitis" brought on simply by the production of too much hyperemia for the relaxed blood vessels to stand. Hamburger says that it has been shown at autopsies that any tuberculous focus in the body is, as a rule, associated with tuberculosis of the bronchial glands and lungs. Could it be possible that the tuberculous processes in the bronchial glands and lungs might precede all other distributions? Hamburger says that scrofula, enlarged cervical glands, tuberculides, phlyctenular ulcers, hygromas, spina ventosa, coxitis, and all tuberculous lesions of the bones and joints presuppose tuberculosis of the bronchial glands and lungs. If so, which is the primary source of infection and which is the metastatic development? If the tuberculous processes in the bronchial glands and lungs represent the primary source of infection, could we by recognizing their presence prevent the secondary development of Pott's disease, spondylitis, psoas abscess, and other bone and joint lesions? If it could be proven that the orthopedic surgeon simply cor-

rected metastases, could we do anything to prevent these migrations?

From the work of Combé and Pollak it appears that our knowledge of concealed or clinically inactive tuberculosis must be applied to infancy and childhood. We have the same world to explore that we find in later life, and the prevention of tuberculosis may have to begin with infants in good health, with no heredity, and no history of exposure.

RELATIVE VALUE OF MASSAGE, EXERCISES, AND BATHS IN THE TREATMENT OF AFFECTIONS OF THE HEART.

By DOUGLAS GRAHAM, M.D.,

BOSTON, MASS.

PRESIDENT OF THE MASSACHUSETTS THERAPEUTIC MASSAGE ASSOCIATION.

"Give me a calm and peaceful heart,
From every murmur free."
—*Old Hymn.*

HARVEY, in 1650, narrated the case of "a man who, in consequence of an injury or an affront which he could not revenge, was so overcome with hatred, spite, and passion that he fell into a strange disorder, suffering from extreme compressions and pain in the heart and breast from which he received some little relief only when at last the whole of his chest was pummeled by a strong man as the baker kneads dough."

Physical or external therapeutics, in contradistinction to medical or internal remedies, have come much into favor in the treatment of disease of the heart in the past few years. These are massage, resistive movements, saline baths, and mountain climbing. Of these, massage is the most generally applicable. It can be used in cases so weak as to preclude the possibility of applying any of the others. In almost every conceivable form of weak and diseased heart I have been called upon to do massage, and usually with marked relief and comfort, before Schott or Oertel were ever heard of. While it was being done, and for some time after, the patients have generally been able to lie on either side or flat on the back, and often go to sleep in this position, what they could not have done before. In other cases, where it was impossible for them to lie down at all, I have masséed with relief until within a short time of their death.

Massage of the chest, over the region of the heart, has a powerfully tonic and sedative effect on this organ, as either physicians or patients can prove by observing its effects in their own persons by means of Bowle's excellent stethoscope. Even a well but lazy heart will be found to beat much better and with a clearer accentuation after a few minutes of massage, reminding one very much of the effect of using the bellows on a fire that burns slowly. This is most marked in the flabby neurasthenics.

The enthusiasm of Professor Oertel over massage of the heart may have gone a little too far, but perhaps this may have been necessary in order to wake up the profession to its great value. In his latest work on this subject he considered that massage acts upon the heart the same way that it does upon the muscles of the extremities. In order to do this the chest wall would have to be removed, so that the heart might be grasped and directly masséed, a procedure that would hardly be justifiable in the human being, except in extreme cases. While the patient stands, he advises that gliding pressure should be made upon the chest walls downward and inward, the benefits of which, he states, "are not only referable to its influence in perfecting expiration, but also to the direct pressure upon the heart, influencing its nutrition precisely as massage benefits the muscles of the extremities." The patient would have to be pretty well to stand while this was being done. The influence of massage over the heart is indisputable, but evidently it must be more indirect and sympathetic than direct. Oertel very properly considers this treatment indicated: "(1) When the heart muscle is weak from deficient nutrition, anemia, or corpulence. (2) When the arterial system is imperfectly filled, and there is passive congestion as a result of insufficiency of the myocardium. (3) When there are valvular lesions or obstructions to the circulation, the pressure of tumors, or constriction of the pulmonary orifice, emphysema, or curvature of the spine. (4) As an accompaniment of treatment of the heart by mountain climbing. It is contraindicated in acute or recurring endocarditis or pericarditis, in acute and subacute myocarditis, the result of sclerosis of the coronary arteries, and in general arteriosclerosis."

I have never seen a case of arteriosclerosis that was harmed in any way by massage, nor have I met any one who has. Such a statement is made on purely theoretical grounds.

General massage, carefully administered, is of great aid to the peripheral circulation, lessens the work of the heart, tranquillizes the nervous system, and induces sleep in the worst kind of heart disease; and massage of the abdomen often works well as a diuretic and to relieve the stasis of the mesenteric veins and all the other abdominal veins.

Next to massage, in its universality of application, and under circumstances in which patients have been too weak to undergo saline baths or mountain climbing, come resisted movements. These, combined with the saline, sparkling waters of Nauheim, were first brought prominently to notice by the Drs. Schott, who up to 1891 had treated in this way 2,700 cases of cardiac disease, mostly with great benefit or recovery. Each resisted movement of extremity or trunk is slowly and completely executed, followed by a pause, after which the opposing movement alternates in the same way, while the physician or person who makes the resistance is ever watchful to avoid anything like fatigue, difficulty of respiration, or increased disturbance of heart; and should such arise, a longer pause is given. Some of the advocates of this method state that no movement is to be repeated twice in succession to the same limb or group of muscles, but I have yet to learn that Schott himself is so absolute in his directions.

The immediate effect of the bath is not quite so marked as after the exercises, but it lasts longer, while the exercises can be used repeatedly on the same day and without regard to place. In illustration of this, the resistive movements were given

to a boy who was weak and anemic. Percussion showed dilatation of the heart. Two skiagraphs were taken, one before, the other fifteen minutes after, a quarter of an hour of exercises of moderate resistance. It was evident that the heart had contracted strongly on both sides, and that it had changed from the shape of an orange to that of a lemon, and was one-half inch smaller by measurement. For the sake of comparison, and in order to ascertain the effect of the Nauheim effervescent baths alone, Dr. Schott had a somewhat similar case, a girl of fourteen years, carried to the bath, and after this back to the table. It was found, as a result of the bath that the heart had contracted about one centimeter (less than half an inch) in its horizontal diameter. This is getting matters down pretty fine.

It has also been shown by Dr. Schott, to the satisfaction of impartial observers, that wrestling until the breathing becomes short or excessive, and bicycling, produced dilatation of the heart and weakened it, from which he has deduced the axiom, "Systematic exercises strengthen the heart, unsystematic exercises weaken it."

Dr. W. Bezly Thorne of London, who has witnessed the effects of systematic resisted movements in many cases, says of them: "The results are such as would scarcely be believed by any but an eyewitness. It is by no means uncommon in cases of dilatation to see within one hour the oblique, long diameter of the heart's area of dullness diminished by from three-quarters of an inch to an inch and a quarter; and, perhaps more surprising still, to observe a diminution by as many as two inches in vertical measurement of a liver which at first extended to the umbilical level, and to hear the patient, at the conclusion of what cannot be considered an ordeal, volunteer the statement that a load has been removed from the precordia, that he breathes easier and more deeply, and experiences a sense of general relief."

When such good results can be obtained from massage or resistive movements alone, it would seem almost superfluous to burden patients with baths besides other than what may be necessary for cleanliness. Indeed, the advocates of the mineralized baths are not very clear in their ideas as to when the one or the other should be used, or when they should be alternated or combined, so that these problems must be left to the discretion of the attending physician, who will be guided by the effects upon the patients. Dilatation of the arterioles and reduction of high arterial pressure may be obtained by slow, deep kneading of the muscles of the system at large; while, on the other hand, increase of the strength of the systole may be brought about by gentle resistive movements of the limbs and by friction or stroking of the limbs and body toward the heart.

The waters of Nauheim consist largely of a solution of chloride of sodium and chloride of calcium with an abundance of carbonic acid gas, and are of varying degrees of strength. Similar combinations are for sale at the drug stores, which can be dissolved in one's own bath tub; but employed in this way, the results are not so favorable as they are at Nauheim, where pleasant scenery, bracing atmosphere, and absence from the cares of home all contribute beneficial influences. The duration of the bath at first should not exceed ten minutes, and the temperature of the water should be about 92° or 93° F. At the commencement, the bath should be omitted every other day, then every third day, next every fourth day. Later, the baths are given oftener and longer, their mineral ingredients are stronger, and the temperature is cooler, down to 88° or 85° F. Though the immediate effect of these sparkling waters conveys the impression of a bath of champagne and induces a sense of exhilaration, yet the first few baths are apt to be associated with a sense of oppression at the precordia, and the patients breathe more slowly and deeply for a few minutes. Respiration then becomes easy and continues slower. When infiltration or deposit has occurred in accessible places, careful massage succeeds the bath. Sometimes the resisted movements are used to prepare patients for the baths, and they should be continued sufficiently long after until the patients can climb mountains. After the completion of the bath and exercise treatment, Dr. Schott says he has seen patients make extensive tours through the Alps, and even climb Mont Blanc and Monte Rosa without any difficulty. Nothing is said about the duration of the treatment. It must vary greatly to suit different cases, and be limited or extended by the convenience of the patient.

It is certain that but few American patients who are well enough to go to Nauheim would be willing to submit to this treatment at home for a sufficient length of time to do any good at all.

Respiratory exercises are often of great value, even when not enforced by the exhilarating exercise of mountain climbing. John Hunter, in the graphic sketch of his own case, stated his belief that he had often prevented himself from dying by deep breathing. Deep respiration alleviates the suffering of many cases characterized by extreme arterial pressure as well as those attended by cyanosis. It probably acts by unloading the right cavities of the heart and by relieving pressure from the aorta (Gibson).

It is emphatically declared that gymnastics or physical exercises by means of mechanical appliances should form no part of the system of resisted movements, and they are even opposed to it as harmful. They ought to be helpful when improvement has sufficiently progressed, especially exercises with elastic cords, as their use gives alternate resisted movements each way.

Possibly the advocates of the saline bath in disease of the heart have not taken sufficient account of the fact that when a body floats in water it is buoyed up by an elastic resistance equal to its own weight, and this presses the venous blood and lymph back to the heart from the parts that are submerged. This is massage by hydraulic pressure of the immersed portions of the body.

According to Fleischi, the shock of the blood sent into the capillaries at each cardiac systole has a mechanical action in aiding the chemical processes of tissue change in somewhat the same way, though to a less extent, as a blow upon a percussion cap. If a heart is too feeble or the resistance in the vessels too great to allow the blood entering the aorta at each systole to give a distinct

forcible impulse to the blood present in the arteries, the chemical changes in the tissues will be sluggish and imperfect. It is therefore of the utmost importance in the treatment of disease to maintain the action of the heart and to stimulate it when flagging (T. Lauder Brunton).

Dr. Douglas Powell[2] helps to define more clearly the use of massage and exercise. He tells us that massage is a means of helping on the convalescent stage of acute heart disease and of combating the tendency to stagnant circulation in those who are disabled by chronic heart disease. The treatment, he thinks, is still more useful in maintaining the circulation and mildly stimulating the coronary circulation in those who are bedridden, and, on that account, suffer from impairment of heart nutrition and chilly extremities, feeble pulse, torpid digestion, and passive congestion of the lungs. The treatment is not advisable in acute affections of the heart.

The effects of the Schott or Nauheim exercises are a stimulation of the heart's action, with a steadying effect or increased completion of the systole, improved circulation through the coronary vessels, and an increased motility of the blood by its readier passage in greater bulk through the muscles, thus relieving stagnation in the great internal organs, especially of their veins. The graduated exercises may be regarded as a counsel of perfection, as a preliminary to the return to this increase of active life of which the condition of their heart admits, and also as a guide to what that measure of exercise will be. Resistive exercises are especially adapted for the initial treatment of those flabby, irritable, "stuffy" hearts, applying this term to cases of fatty infiltration and impaired metabolism which are met with in people of venous plethora. Irritation of a sensory nerve causes general contraction of blood vessels.

In cases of chlorosis with dilated heart, after a preliminary week or two of rest, the Schott treatment is valuable if combined with a dry, bracing air and a mild chalybeate. It is useful in commencing failure of the heart, in chronic valvular lesions, combined with less of other exercises, and also after such cases have been restored to a certain extent by digitalis. It is unsuited in all cases of acute endocarditis while there is any trace of activity of lesion left, and in cases of advanced cardiovascular changes of the nature of sclerosis, or in introspective people with neurotic hearts.

An excellent summary of this treatment of heart affections was given by Sir Grainger Stewart before the British Medical Association at Carlisle. He has fully satisfied himself on the following points:

1. That in the great majority of cases of cardiac dilatation the area of cardiac dullness diminishes perceptibly during each administration of massage.

2. That the character of the cardiac sounds and the rhythm and strength of the pulse correspondingly improve.

3. That although the immediate favorable effects pass off in a few hours, yet they frequently do not pass off completely, for he has often found the line of cardiac dullness within that with which they had started at the previous séances.

4. That the patients usually experience a sensation of comfort and feel the better for the treatment.

5. That repeated applications of massage bring about a permanent diminution of the area of dullness, with improvement of pulse and of the patient's sensations.

6. He has seen a case in which the so-called Schott treatment produced deleterious effect, rendering the heart more irregular and intermittent. It was afterward treated by massage alone on the following day with most striking benefit. It turned out that the patient was not sufficiently well to bear the active movements, but was greatly benefited by the passive ones.

7. That on one or two occasions he has seen the manipulations produce unfavorable effects, apparently because the heart was too feeble and the patient was fatigued at the time of application.[3]

(In this last case it is possible that the massage was too vigorous, or that the manipulator himself was not in good condition. The writer one day had to walk three-quarters of a mile in the teeth of a cold wind to give massage to a patient with a weak heart. The result was the only unfavorable one of the kind he had ever had: the patient was unduly fatigued. If he could have ridden to the patient's door, the result most likely would have been different.)

Dr. Albert Abrams[4] finds that any cutaneous stimulant—mechanical, chemical, or electric—will produce diminution of the size of the heart with temporary dilatation of the lungs. Vigorous cutaneous friction by means of a wire brush seemed to afford him results in heart disease nearly as good as those obtained by the more elaborate treatment by means of baths, massage, and exercises. He quotes Moccucci, who sprayed the left half of the abdomen with ether in twelve cases of enlarged spleen with the result of decrease in volume of the spleen in all the cases. In repeating these experiments, Dr. Abrams noticed a decided diminution of the size of the spleen in all the people he tried it on, irrespective of the fact whether the spleen was enlarged or not. Ether spray over the heart and over the liver caused decrease in size of both these organs. The results were confirmed not only by percussion, but also by sight, by means of the fluoroscope.

Maas[5] has reported two cases in which patients apparently dead from chloroform syncope were resuscitated by compressions in the region of the heart. In both cases, respiration and radial pulse had entirely stopped, and the pupils were dilated. The manipulation of the heart in both cases was carried out for over an hour. Compression over the heart was used one hundred and twenty times a minute, and soon after it was begun the pupils became smaller and the paleness of the face disappeared. Afterward both patients suffered from mental derangement, difficulty of swallowing and speaking, all of which passed off shortly.

Doubtless sufficient importance is not always attached to the fact that collapse is often due to sudden relief of the intraabdominal pressure.

Physiologists have not been idle in their efforts to show how weak and failed hearts may be revived; indeed, some good men give them credit for leading the way.

If any more confirmatory testimony of the efficacy of massage for weak hearts were needed, we certainly have it in the experiments of Professor Prus,[6] in which dogs were suffocated and brought back to life by massage of the heart. The supply of air was shut off by clamping an India-rubber tube which connected the tracheotomy cannula with an artificial respiration apparatus. Immediately after the death of the animals some of the rib cartilages in front of the heart were removed, the pericardial sac was incised, and the heart exposed. After it had been ascertained that there was no trace of any contraction of either auricle or ventricle, Professor Prus waited fifteen to sixty minutes before he began his efforts at artificial resuscitation. Then the clamp was removed and artificial resuscitation started. The heart was grasped in the right hand so that the thumb rested on the right ventricle, and the four fingers surrounded the left ventricle. Both ventricles were then compressed with moderate force, the compressions being made to imitate the systolic and diastolic action of the heart. In 31 cases, or 70 per cent., life was restored. In chloroformed dogs under the same conditions, 76 per cent., and in dogs shocked by the electric current, 14 per cent. were brought back to life. An attempt to try massage of the heart was made on the body of an alcoholic who had committed suicide by hanging, but without success, as might have been expected.

Statistics gleaned from various sources at home and abroad by Prof. William W. Keen[7] show that of 28 cases of apparent death in the human being, during chloroform narcosis, four recovered by massage of the heart. But this treatment should not be relied upon alone. Artificial respiration should also be carried on and the patient should receive sufficient oxygen. For the purpose of restoring vasomotor tone adrenalin should be employed.

In the great zeal to collect statistics on this interesting subject, doubtless many of them come from the same sources. Thus Lanermant[8] has collected 25 cases, of whom 4 were restored to life Mauclair and Zezas report 28 cases with 6 successful results.

Three methods are employed to do massage of the heart:

1. Incising the anterior wall of the chest so that the hand can grasp the heart.

2. Incising the diaphragm and then passing the hand up from the abdominal cavity.

3. Seizing the heart through the diaphragm without cutting it. In syncope the diaphragm is relaxed enough to render the last method easy. It has given the greatest percentage of recoveries (5 out of 9). It is the least mutilating and the only one that should be employed. Although the number of deaths seems large, it should be remembered that all the cases saved would doubtless have died without the use of this method.

When babies are born, if their respiration and circulation are at fault, they are promptly rubbed and slapped without waiting for a diagnosis, and usually with the result of bringing them around all right. So the poet of the future may have a chance to express himself with regard to massage somewhat as follows:

When this world you enter, if you're gasping for breath,
'Tis the first thing they do to save you from death;
If too soon you would leave this terrestrial sphere
'Tis the last thing they do to keep you long here.

INSTRUMENTS OF PRECISION FOR THE PERCY TREATMENT OF UTERINE AND OTHER CANCER.*

A. THE ELECTROPYROMETRIC HEATER.
B. THE DISTENSIBLE HYDROTHERMOTAXIC HEATER.

BY A. ERNEST GALLANT, M.D.,
AND
L. HOWARD MOSS, M.D.,
NEW YORK;
PROF. LOUIS BLISS AND E. N. LIGHTFOOT,
WASHINGTON, D. C. NEW YORK.

THE purpose of this communication is to present for your inspection and consideration two newly designed instruments for the accurate application of a low degree of heat (Percy's method) for the devitalization and destruction of cancer involving the uterus and vagina, the alimentary tract and other cavities.

It is to J. C. Percy[1] of Galesburg, Ill., that we owe a debt, as the first to apply, in a curative way, the well established principle that the continuous application of a relatively low degree of heat, 43° to 46° C., when delivered directly into the cancer mass, for from 20 to 60 minutes, will cause a disintegration and destruction of the malignant tissues to a depth of from two to three or more inches outside the point where the heat is applied, and that without injury to any of the contiguous healthy structures.

In thus applying heat, Percy made use of an electrically heated plumber's soldering iron, the copper heads being modified in shape to resemble the tips of a Paquelin cautery.

When we take into consideration the facts that most of Percy's patients were "of the utterly inoperable cases, the kind with 100 per cent. mortality,"[2] with some alive after two, three, four, and even seven years, we must admit that the method has a definite place in the treatment of uterine and vaginal cancer. In brief, Percy's technique is: (1) Open the abdomen. (2) Use a low degree of heat. (3) Pass the heating head through the cervix to the fundus; keep it in one position until the whole mass contiguous to the heating iron is made so hot that it cannot be held longer in the surgeon's hand when incased in a medium weight rubber glove. (4) Apply the heat until all the structures that

*Read at the eighteenth annual meeting of the American Therapeutic Society, held in New York City, June 1, 1917.

were fixed at the beginning of the application are freely movable.

After witnessing Percy demonstrate his method at the General Memorial Hospital, and listening to his paper[3] before the Academy of Medicine, New

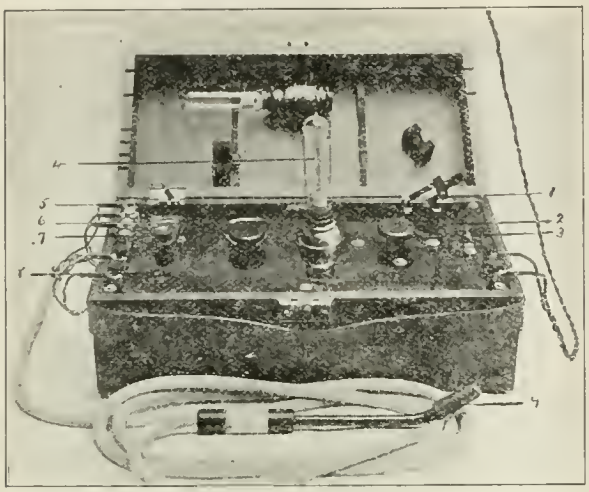

FIG. 1.—Electropyrometric heater: 1, heating switch; 2, rheostat; 3, fuse; 4, resistance lamp; 5, test switch; 6, galvanometer "tell-tale"; 7, temperature setting handle and scale; 8, galvanometer button; 9, copper heating head.

York, April 15, 1915, and a careful consideration of his technique, one could not but be impressed by (*a*) the absolute sincerity of the operator; and (*b*) the possibility of rendering the immobile uterus freely movable, and that without any apparent depressing effect on the patients at the close of about an hour's application in each case.

After some months of study and fruitless efforts, my associate, Dr. L. Howard Moss, was successful in interesting, from a humanitarian standpoint, the generous services of Professor Louis Bliss, of Washington, D. C., who, from our crude drawings, developed the pyrometric heater herewith shown you, and formerly presented[4] to the Medical Association of the Greater City of New York, June 15, 1916, which has been named the "Electro pryometric heater," and offers the following special features (Fig. 1):

1. For *heat localization* a specially designed heating coil placed in the ½ x 2-inch copper head wherein all the heat is generated and localized within the cancer mass, the handle remaining cool.

2. *Introduction* through an ordinary bivalve speculum has been made easy, as the head has been united with the handle at an angle similar to that of an uterine sound.

3. *Heat measurement* has been accomplished by inserting in the head the wires of a thermocouple that registers the actual degree of heat generated in the head, which can be adjusted to any temperature between 100° and 200° F.

4. *Heat control* is obtained by "setting" the regulator at the desired temperature, turning the rheostat and pressure on the "tell-tale" which will indicate if the heat being delivered in the head is above or below the desired degree.

5. *Heat safety* is insured by a very delicate fuse protecting the patient and instrument from short circuiting.

6. *Heat dissemination* can be facilitated in the enlarging cavity, as the treatment progresses, by slipping over the head metal caps ¾ and 1 inch in diameter.

7. *Heat radiation*—From our limited experience in one human patient, and numerous experiments with animal and vegetable tissues, we find that owing to the rapid distribution of heat from the considerable area of the surface of the head, there is a difference between the internal and external temperatures of from 15° to 20° F.

The following is the report of a case of inoperable epithelioma of the cervix, uterus and broad ligaments, treated by the pyrometric heater:

Mrs. C——, aged 47, multipara, last menses four years ago. For the past nine months has had a bloody vaginal discharge, with a very bad odor; alternating constipation and diarrhea; dysuria. "The pain is wearing her out." She had made arrangements to enter a home for incurables, but learning of the "heat" treatment, entered the service of Dr. N. C. Goodwin, at the Jamaica Hospital, who made a cystoscopic examination and found disseminated ulceration of the vesical base. Examination showed that the cervix had been removed, leaving an inverted cone leading into the uterine cavity, but 2 inches to the fundus, and the whole firmly fixed by the thickened broad ligaments out to the pelvic walls.

Jan. 3, 1917.—The first "heating" lasted an hour, with the galvanometer "set" at 138 F., and the heat developed in the uterus at 106° to 108° F. One hour prior to the treatment a hypodermic injection of morphine, gr. ¼, hyoscine, gr. 1/100, and cactin, gr. 1/67. At first she was a little nervous, but dozed from time to time, occasionally complaining of backache, which she attributed to the lithotomy position. The application was made through an ordinary Graves' bivalve speculum. During the following week she lost considerable blood, but the vaginal odor was much less evident. Jan. 17.—The vault presented a craterlike appearance. The heating lasted one hour, at the same temperature as before, and during the next three weeks the bleeding stopped, the odor was no longer obnoxious, pain lessened, the appetite and sleep were markedly improved, and she sat up almost daily. No morphine was given for pain after the first treatment, but she was very homesick for her children. Feb. 3.—The excavation has nearly doubled in size, the edges of the vaginal vault came together when the speculum was removed, and we felt greatly encouraged at what was being accomplished. The third heating of one hour was given, but a few days later her friends (?) took her from the hospital to the home for incurables, though it was evident to all who saw her that she was improving in every way. We have no opportunity to follow up the case.

However, we had learned (*a*) that a temperature as low as 108° F. would and did devitalize can-

FIG. 2.—The distensible hydrothermotaxic heater: 1, water pan; 2, heat regulating switch; 3, motor driven pump; 4, double current applicator enclosed in a rubber bag; 5, glass tube, enclosing thermometer 6.

cer tissue; (*b*) that it would stop hemorrhage and odor, and lessen pain; (*c*) that it was followed by absorption and temperature; (*d*) that the patient's condition improved in every respect; and (*e*) that with the pryometric heater the heating could be

made without anesthesia, through a bivalve speculum, without opening the abdomen; and last, but not least, that though our instrument was built to develop 140° F. in the heating head, it would have to be changed to attain a much higher temperature; and that only experience can demonstrate just what the temperature will have to be to deliver 120° F. (or higher) into the tissues, the degree which Percy seems to imply is necessary to penetrate deeply into the tissues, and destroy the whole of the pelvic neoplasm.

We can but feel that with the right degree of heat, applied through the pyrometric heater, the local destruction of cancer can be effected.

While the pyrometric heater was in course of construction, I became obsessed with the idea that the use of hot water as a heat conductor might afford several advantages, and, through the untiring efforts of Mr. E. N. Lightfoot, herewith we present, for the first time, the result of the past two years' work, which has been christened (Fig. 2) "The distensible hydrothermotaxic heater," the components of which are:

A *water heating system* consisting of a pan (1) holding about a quart of water, under which are fastened electric elements for heating the water; and (2) a heat regulating switch which controls the current and the temperature of the water.

A *pumping or circulating system*—The heated water from the pan is forced by a motor-driven pump (3) through tubing and the double-current applicator handle, filling and distending the rubber bag (4) and returning through the handle, follows the tubing back to the water pan. The pumping and heating are accomplished by the same 110 to 120-volt, direct or alternating street current.

The *heat regulation* can be accomplished by (*a*) by increasing the electric current to the water pan; (*b*) by speeding up the pump and accelerating the flow of water through the applicator, or (*c*) by combining these two methods.

Heat Determination—Borrowing the ingenious idea from J. J. Tate[5] a glass tube (5) inclosing a thermometer (6) has been connected up with the tubing before the water enters the handle of the applicator, and as it surrounds the thermometer in the glass tube, it permits the operator to see the exact temperature of the water as it enters (or leaves) the applicator.

For determining the degree of heat being *delivered to the tissues* a curved thermometer is placed between the tissues and the bag within the mass, and the reading will show the heat being delivered to the *tissues at the point of contact.*

Advantages of the water distended applicator for the application of water-borne heat in the treatment of cancer—The novel and most important feature of this apparatus is the dissemination of water-borne heat, through a distensible rubber bag, a method which we believe offers the following practical advantages:

1. *Insertion*—With the rubber bag collapsed the applicator can be easily introduced into a moderately dilated cervical canal, or through a stricture of the esophagus, pylorus, or any other portion of the alimentary canal (after opening the gut).

2. *Adaptability*—Under the internal pressure of the pump-driven water the bag will distend and adjust its size and shape to every nook and corner of any canal, cavity or excavation.

3. *Dissemination*—As water is the best heat conductor, and the thin-walled rubber bag in actual contact with the tissues, we have the most favorable conditions for the uniform dissemination and the deepest penetration of the necessary degree of heat, throughout the widest possible area, and for securing the greatest disintegration and destruction of the malignant structures.

4. *The technique* is of the simplest, requiring only a bivalve or Ferguson speculum; the introduction of the collapsed applicator; the raising of the water to the required temperature; the adjustment of the pumping to the necessary speed; and to keep it going for 30 or more minutes, or until the rigid mass has become mobile.

5. *Drainage* must be efficient to avoid absorption and can best be secured by inserting one of our two or three-inch fenestrated rubber drains, with a roll wick,[8] the latter to be changed from day to day.

6. *Subsequent treatments* can at any time be carried out, and as frequently the condition seems to indicate; as the whole procedure can be accomplished without anesthesia; without opening the abdomen; without pain or discomfort to the patient, simply by the injection of morphine, one-quarter grain; hyoscine hydrobromide, 1/100 grain, cactin, con. 1 67 grain, one hour before operation, and repeated if necessary.

Favorable reports have been made by Clark[7], Gelpi[8], and Balfour[9], who says: "Percy has developed a method which derives the full value of this agent (low heat) in the treatment of cancer of the cervix. I became interested in this method about two years ago and from experience in more than 100 cases am convinced of its great value. . . . The method undoubtedly offers more to the patient with advanced cancer of the cervix than any treatment with which I am familiar. Its value is so definite in the advanced stages that serious consideration must be given its possibilities in the earlier stages of the disease." If we accept these reports, then with the pyrometric heater and the hydrothermotaxic applicator, or both, we certainly ought to be enabled to avoid the not-unlooked-for results reported by Boldt[10], and Leonard and Dayton[11], where the pathological reports seem to point unmistakably to the need of just these instruments of precision which we now offer you.

From the experience of Fulton[12] with heated bougies for gonorrhea; the use of hot water in urethral stricture, by Stern[13], and our own experience[14] with a double current pelvic cooler in pelvic peritonitis, proctitis, etc., it would seem that the field of usefulness for the distensible hydrothermotaxic heater may be a widely useful one.

Medicolegal Notes.

Registration of Osteopathic Physicians.—The Illinois Supreme Court holds that one who practises osteopathy pursuant to the certificate of the State Board of Health authorizing him to treat human ailments without the aid of medicine and without performing surgical operations is a physician entitled to registraton under Section 15 of the Illinois Vital Statistics Act of 1915. It holds that the term "medicine" is not limited to substances supposed to possess curative or remedial properties, but has also the meaning of the healing art—the science of preserving health and treating disease for the purpose of cure—whether such treatment involves the use of medical substances or not. In common acceptation, any one whose occupation is the treatment of diseases for the purpose of curing them is a physician, and this is the sense in which the term is used in the Illinois Medical Practice Act. An osteopathic physician is a "legally qualified physician" under Section 7 of the Vital Statistics Act, which provides for death certificate and requires that the certificate shall be made and signed by the "legally qualified physician," if any, last in attendance, or, if none in attendance, by the coroner or the local registrar. If such a physician is legally qualified to treat the disease the court considered there is no reason to suppose that he is not legally qualified to give the medical certificate required by the act. The statute authorizes osteopathic physicians to treat human ailments without the use of medicine and without performing surgical operations, and the court holds that under such authority they may treat cases of pneumonia, gastritis, rheumatism, paralysis, and other diseases. The purpose of the Vital Statistics Act is to provide a system of registration of births and deaths throughout the State.—People vs. Siman, 115 N. E. 817.

Authority for Coroner's Inquest.—An illinois statute requires a coroner, whenever or as soon as he knows or is informed that the dead body of any person is found or is lying dead in the county supposed to have come to his death by violence, casualty, or any undue means, to summon a jury and hold an inquest to inquire into the cause and manner of the death. The Illinois Supreme Court holds that under this statute a coroner was not authorized to hold any inquest over the body of one who died under the care of a physician, of tuberculosis of long standing, there being no supposition that he came to his death by violence, casualty, or any undue means.—Albaugh-Dover Co. vs. Industrial Board, 115 N. E. 834.

Following Particular Schools of Medicine.—In an action for malpractice the issue was whether the defendant was guilty of malpractice in giving a diet of poached egg and toasted bread to a typhoid fever patient. It appeared that the patient's diet was changed from one of beef broth. After the change of diet the patient appeared to be worse, and his wife had him removed from the hospital where he was being treated to her home where he was treated by a homeopathic doctor. He died two days after the removal. The evidence showed that his death might have been due to one of three causes: First, the disease itself; second, the carrying of the patient from the hospital to another place; and, third, the change of diet. The court held that it was for the jury to determine which of these causes resulted in his death. One instruction told the jury that if the defendant did not follow the practice recognized by other physicians in good standing in that locality, and as a result thereof hastened the deceased's death, recovery could be had. The court held that this is not the law. The evidence showed that the defendant was an allopathic doctor. One of the doctors who testified that the treatment given by the defendant was improper was a physician of the homeopathic school. The court said: "Each school of medicine is entitled to practise in its own way, and because one does not use the methods of the other is no reason for holding the one for malpractice. In the case of Dahl vs. Wagner, 87 Wash. 492, 151 Pac. 1079, we said: 'It has been the uniform holding of this court that where doctors of equal skill and learning, being in no way impeached or discredited, disagree in opinion upon a given state of facts, that the courts cannot hold a defendant in a malpractice suit to the theory of the one to the exclusion of the other. This is the logic of Brydges vs. Cunningham, 69 Wash. 8, 124 Pac. 131. It is enough if the treatment employed have the approval of at least a respectable minority of the medical profession who recognize it as a proper method of treatment. Lorenz vs. Booth, 84 Wash. 550, 147 Pac. 31. The reason is obvious. A man who is called upon to exercise professional judgment is bound only to the exercise of reasonable skill, learning, and diligence. He is not liable for mistakes if he uses the method recognizd and approved by those reasonably skilled in the profession.' Before recovery could be had the jury ought to have been told that the defendant did not use his judgment in administering the egg and toast, under the circumstances." Judgment for the plaintiff was reversed and a new trial granted.—Ennis vs. Banks, Washington Supreme Court, 164 Pac. 58.

Medical Works As Evidence.—Scientific books are not admissible in evidence as proof of the facts they set forth, but if a witness assumes to base his opinion on such books, extracts may be read from them to contradict him. Having expressed an opinion upon a matter material to the issue, a medical expert witness may be crossexamined whether that opinion is based upon personal experience or upon books which he has read, and this whether or not he has stated in his direct examination the basis of his opinion. Should he testify for the first time upon crossexamination that his opinion is based upon what he has read, counsel has the same right to interrogate him as to the authorities upon which he relies, and then contradict him with those authorities, if he can, the same as if he had testified in direct examination that his opinion was based upon such authorities. The mere fact that the witness on direct examination has expressed his opinion generally will not foreclose counsel, upon crossexamination, from eliciting from the witness the basis of his opinion.—Wilcox v. International Harvester Co., Illinois Supreme Court, 116 N. E. 151.

Duty of Sanitarium to Patients.—The Arkansas Supreme Court holds that the proprietor of a hospital or sanitarium is bound to give a patient reasonable care and attention, and to have that knowledge of the necessities of his case which would result from such care and attention, and from the possession of ordinary skill in his treatment, and, though he does not contract for the services of a special nurse, is bound to see that the patient has such attention as his condition apparently makes necessary, and is liable for damages if his failure to perform such duty results in injury to the patient.—Durfee v. Dorr, 186 S. W. 62.

Degree of Care and Skill—Proof of Standard.—On appeal from a judgment for the defendant in an action for malpractice in diagnosing and treating an ailment from which the plaintiff was suffering, the only question was as to the correctness of an instruction given the jury as follows: "In considering whether the defendant, in his diagnosis, care, and treatment of the plaintiff's injury or disease exercised ordinary care, you cannot set up a standard of your own, but must be guided in that regard solely by the testimony of the physicians, and if you are unable to determine from the testimony of the physicians what constituted ordinary care and skill under the circumstances of this case, there would be a failure of proof upon the only standard for your guidance, and the evidence would be insufficient to warrant any verdict for the plaintiff." It was held that the instruction was correct, and judgment for the defendant was affirmed.—Norkett v. Martin, Colorado Supreme Court, 165 Pac. 256.

Military Medicine.

TRENCH FEVER.

By B. SHERWOOD-DUNN, M.D.,

PARIS, FRANCE.

OFFICIER D'ACADÉMIE, MEMBRE CORRESPONDANT, SOCIÉTÉ OBSTÉTRIQUE ET GYNÉCOLOGIQUE DE PARIS; SURGEON (COLONEL), SERVICE DE SANTÉ MILITAIRE DE PARIS, PHYSICIAN TO COCHIN HOSPITAL.

DURING the summer of 1916 there presented themselves at some of the hospitals in the zone of the army a number of patients suffering with a malady having certain distinct and characteristic symptoms which marked it as differing from anything heretofore encountered or described, and which was first called to public attention by Dr. Morichau-Beauchant,[1] who detailed the history of eight cases.

The disease presents a clinical history that is sharply defined and readily recognized.

In the first period, without any premonitory symptoms, the subject is suddenly seized with a sharp, abrupt rise in temperature of two or three degrees Centigrade, an intense headache located in the frontal and occipital regions, marked malaise, fatigue, and pains in the bones, but, with the exception of an enlargement of the spleen and a certain accumulation of viscid mucus in the intestinal tract, no visceral signs.

The second period is marked by a rather regularly defined course of fever, separated by intervals of apyrexia; this may be continued over a period of several weeks.

The third period is marked by a subfebrile temperature which may equally exist for several weeks before the patient is freed from the attack and resumes his normal condition.

All of the cases present a temperature curve that is characteristic and remarkably uniform. The clinical history of these cases shows no marked variation one from the other, and presents a picture easily recognized.

The period of incubation, as nearly as can be defined by the patient, is from five to seven days, and is not sufficiently marked by a deviation from the normal seriously to attract the attention of the subject; all he can be persuaded to recall is that he felt some slight malaise.

The onset is always the same, marked by a chill, severe headache, intense fatigue, and the same day, or day following, a fever reaching 39° to 40° C. (102.2° to 104° F.); the dominant symptoms are the fever, fatigue, and ache in the bones.

The headache which marks the onset is of abnormal intensity, referred either to the forehead or occiput; it presents several recurrent paroxysms, and often the patient will complain of photophobia. The patient never ceases to complain of pains in the lower limbs and in the lumbar region, and shows great prostration. The pains in the limbs, at first vague and diffuse, at the end of two or three days become fixed and precise, and are referred to the bones of the lower leg and the thigh. These pains are characteristic, and one of the constant signs by which the disease manifests itself. The pain is the most pronounced in the lower epiphyses of the femur and upper epiphyses of the tibia. They are more pronounced by spells in the night; the patient complains of a gnawing, stinging pain which robs him of sleep; they are irregular in duration, and may be declared over a period of weeks.

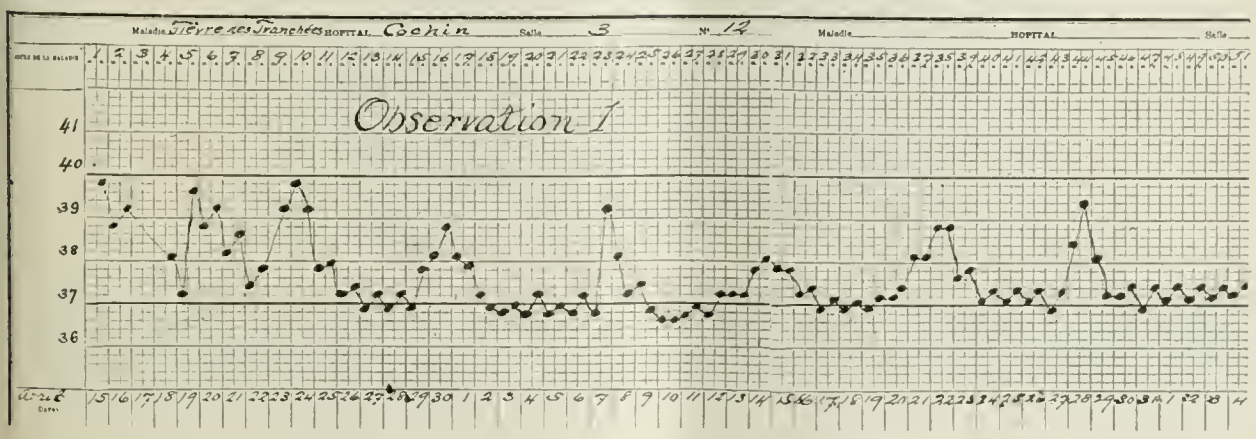
In Charts 3, 4, and 5 the temperature returns to normal the third day. In Charts 1 and 2 the onset is for a longer period; but in every instance, when it falls to normal after the onset it almost at once presents a second access and again mounts to 39° C. (102.2° F.) or more, when it again almost at once begins to recede to normal, with a third access, and sometimes a fourth, when it subsides to normal or subnormal. In Chart 6 the first period of recession is maintained a longer period than in the previous observations.

Besides the fever and rachialgia, the symptoms of lesser prominence can be grouped as follows: Coated tongue, loss of appetite, constipation. There are no visceral symptoms other than a swollen spleen, no vomiting, no diarrhea, no swelling or tenderness over the liver. The pulse in relation to the fever is more frequently lower than otherwise. There are no chest symptoms, except once in a while some slight evidence of a preexisting bronchitis. Besides the intense headache there exists with fair constancy a marked accentuation of the vasomotor response, but no other phenomenon attached to the nervous system.

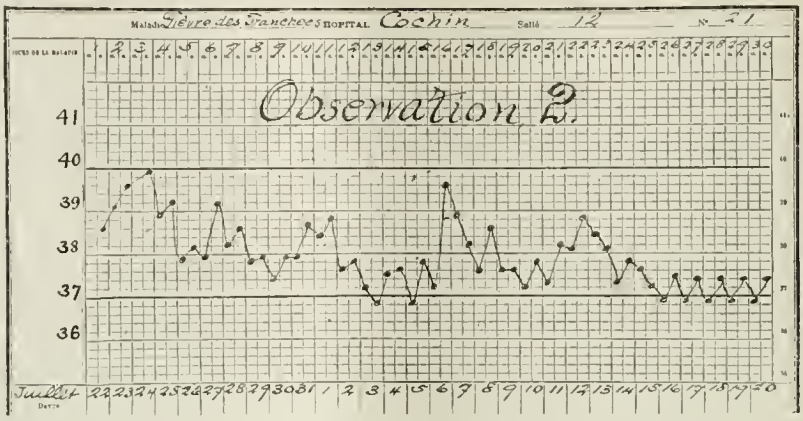
There is absence of sugar and albumin in the urine; sometimes there appear isolated vesicles, apparently resulting from the profuse perspiration.

Following the fall in temperature the patient appears quite relieved, and apparently the attack is over. He recovers his appetite, the pains in the bones subside, and he sleeps well; but from the third to the fifth day he has a repetition of the accidents.

He is again seized by a chill, intense headache,



the lumbar pains and those in the legs redouble in intensity, the temperature jumps at once to 38.5°, 39°, even to 40° C. (101.3° to 104° F.); in short, we have a repetition of all the symptoms which marked the invasion of the malady. This attack continues



two, sometimes three days, then the temperature returns progressively again to normal, and all the troubles again disappear. The fall in the temperature is always marked by profuse sweats; these return also during the quiescent intervals and chiefly at night.

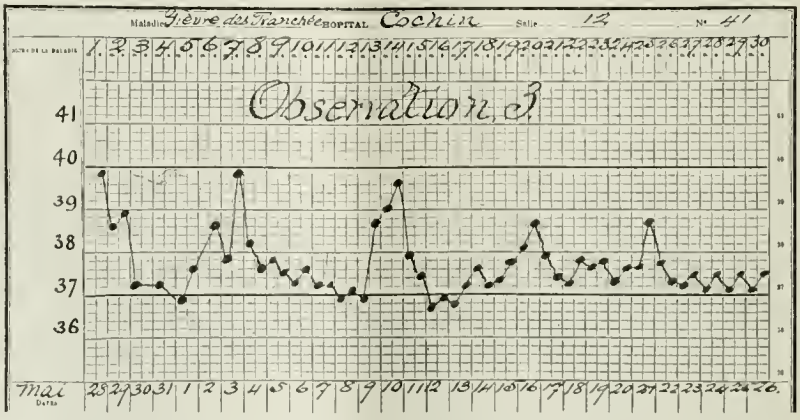
As a rule, the intensity of the symptoms diminishes with each access of the series to the end of the attack, the duration of which varies from fifteen days, as shown in observation No. 4, to forty-four days in observation No. 1. During the intervals between the accessions the patient, as a rule, feels fairly well, and believes his trouble is over. But almost all cases complain of a continuation of pains in the limbs, increased in intensity at night, and accompanied frequently by headache and night sweats.

When finally the attack has spent itself it cannot be said that the subject is freed, for in every case there is a subfebrile period lasting several weeks. During this period all of the symptoms having almost wholly disappeared, the patient's appetite returns, he begins to gain in weight, the spleen returns to its normal size, and there remains only a certain degree of general feebleness. He cannot remain standing any length of time without fatigue, the pains in the limbs persist, but without disturbing the sleep.

Etiology.—It is interesting to note that all of the eight cases cited by Dr. Morichau-Beauchant came from the same sector of the army, where there is a marked absence of swampy or marshy land; there was no complaint as to the presence of mosquitos, but these men, like most of those in the front line, were afflicted with body lice.

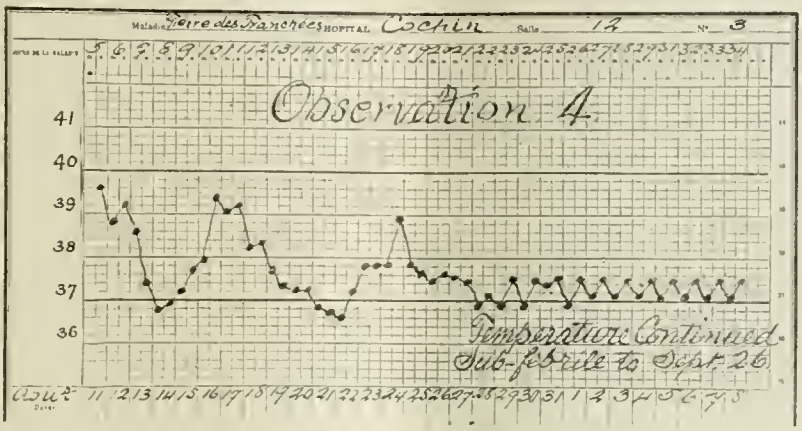
The clinical history presented by the cases shows that they were all suffering from the same malady, but as to just what it was is difficult to determine. It is not an abnormal type of typhoid or paratyphoid, as shown by the absence of all gastrointestinal symptoms, the character of the fever, and the negative results attending repeated examinations of the blood. It is not grippe, for none of the cases presented any thoracic symptoms, and the rapid succession of the attacks does not belong to the character of this disease. Several examinations were made of the blood at the different renewals of the symptoms without finding the presence of hematozoa.

A circular from the Medical Inspectors' office of the French Army calls attention to a new disease appearing in the English Army in Artois and Flanders, to which the name was given of "Trench Fever," and an examination of the published reports[2] revealed this same train of symptoms as observed in the cases here mentioned, excepting that



those observed by our English colleagues seemed to be of a lighter type; none of the symptoms were as severe as in the cases here described which seem to be more profoundly marked, the duration of the disease being more prolonged with a greater num-

ber of accessions. The subfebrile state following in the French cases was not noted in the English ones, and the spleen in the English report was expressly mentioned as not being affected. They also divided their cases into two classes; one the extended, the other the short type of the disease. The prolonged class of cases corresponds in every respect with those here described, especially in the number of relapses. The short form offers the same clinical symptoms, with a fewer number of relapses.



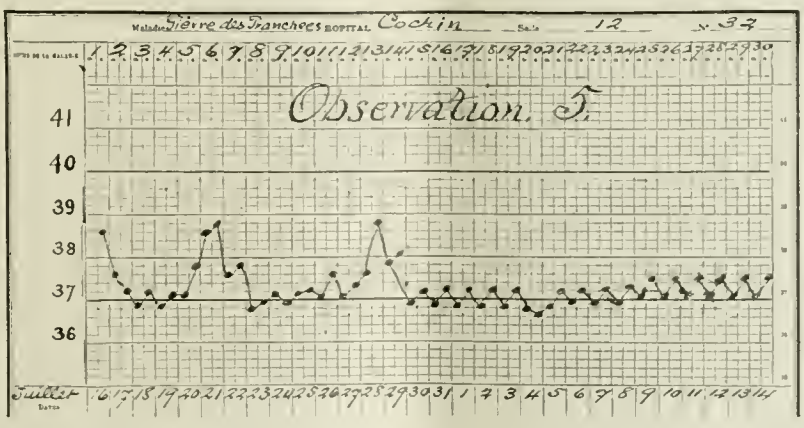
A number of cases similar in character to these were reported at a monthly meeting of the Surgeons of the Fourth Army (Sept. 8, 1916), where the symptoms were typical of those here described, only none gave a history of repeated return of the access and the prolongation of the malady; and it is the length and number of repeated attacks which Dr. Morichau-Beauchant insists on as distinctive of and marking the disease as some new form of malady.

It would appear that the doctor and also the English authors made extensive laboratory researches with cultures of blood specimens in bile, bouillon, and anaerobic cultures, without result; nor were they more successful with cultures from urine, feces, and nasal and pharyngeal mucus. The direct microscopic examination of the blood by aid of various staining agents disclosed neither bacilli, spirilla, nor hematozoa. The blood count also furnished no satisfactory results. The red corpuscles were not diminished; some inclosed basophilic granules; the white corpuscles were slightly increased, but there was no decrease in the hemaglobin.

The English authors sought to discover if the disease was transmissible, and inoculated several soldiers who volunteered for the test. They found that the intravenous injection of 10 c.c. of blood taken from an infected patient reproduced the same train of symptoms after a period of incubation of eight to nine days; and the blood of those inoculated again injected into a healthy subject reproduced the disease up to the fourth series of those subjected to the test. A number of inoculations with the serum or plasma of the blood produced no result; but the red corpuscles, even after washing five times in normal salt solution, still produced the disease, showing conclusively that the elements of infection are found therein.

It was also discovered that the body lice taken from a patient suffering from the disease and placed upon a healthy subject, would transmit the infection.

Certain features of this malady are a duplication of those which mark "military fatigue," a phenomenon which frequently presents itself in the front-line hospital and sometimes deceives the attending surgeon by the intensity of the symptoms and likeness to those which characterize certain well-known diseases. As my conclusions may not be in full accord with those of my French and English colleagues, as to the classification of this new disease called "trench fever," and as I believe fatigue not only plays a considerable and important rôle in the clinical picture, but is in a degree explana-



tory of the phenomena presented, I will enter into a brief description of its characteristics.

It is understood that the soldier's life is as a rule out of the ordinary and under many conditions is calculated to reduce his resistance to fatigue; excessive hours of labor, exposure to all sorts of weather, uncomfortable surroundings, alimentation but slightly varied and often indifferently prepared, long stretches of duty without that period of repose that is of real reparative value, producing a chronic state of fatigue that becomes an important factor in disease, and has been repeatedly noted.[3]

A strong man who has for hours been posted in a position subject to constant bombardment with shells bursting around him; or a man who has been one of a company holding a position against assault, repeated several times during his tour of duty; or the man holding an observation post beyond the front line, with a telephone which he must answer and by which he must constantly report the slightest movement of the enemy, movement of aviators, point, kind, and quality of battery action, and at any moment liable to capture by a rush of the enemy, such a man has his nerves for hours put upon tension. His service terminated, he seeks rest and repose to fit himself for the next call, but does not secure it. His sleep is restless, and unrefreshing; his appetite is poor, as is also his state of digestion, and often there is a passing constipation or diarrhea. He returns to his post unrecuperated and fagged, but brings his will to play and does his full duty, a good soldier. This continues for a longer or shorter period of time, according to the native mental and physical make-up of the man.

One day, brusquely, and without warning, he has a high temperature, 38.5-39°, even 40° C. (101.3°-104° F.); he complains of pains all over, in his head, back, and legs—frontal and occipital headache, rachialgia, and myalgia; he has chills, coated tongue with a distaste for food, but demands drink. The headache is almost always accompanied by vertigo and roaring in the ears; the eyes may be bloodshot. The myalgia is most pronounced in the hips and legs, and not infrequently the patient complains of pains in the joints; nausea and sometimes vomiting are present.

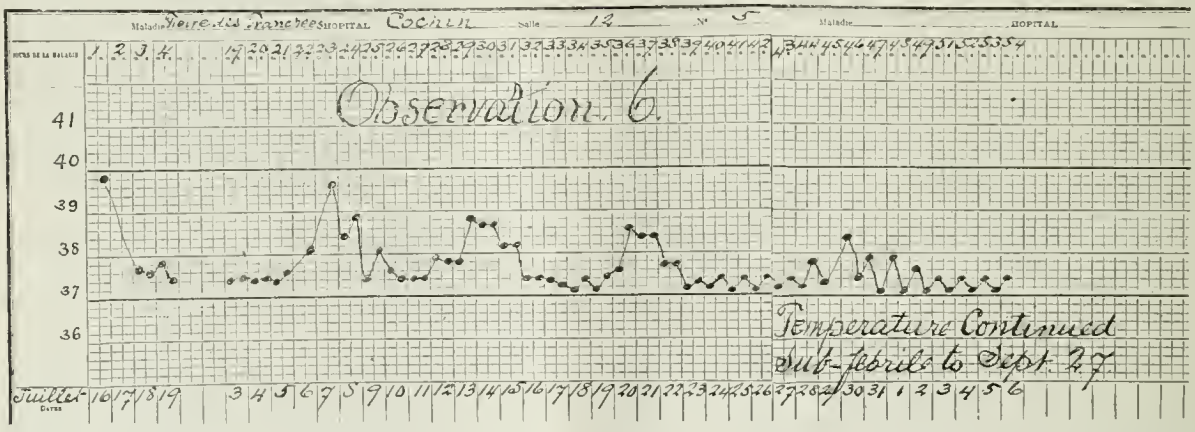
The man may have diarrhea, but more frequently constipation. His pulse is accelerated and in keeping with the temperature, his face is haggard and usually a hectic flush covers the cheeks, although he may be abnormally pale; his eyes are brilliant and restless, or heavy, lusterless, and dead. Some give a history of epistaxis and sometimes vesicles appear upon the lips.

These symptoms last from three to six days. The temperature oscillates, but under the influence of a brisk purge (if constipated) and quinine, falls to normal—in the bad cases possibly to subnormal; but the pains in the bones and muscles persist, and the patient shows great fatigue—even prostration, which usually disappears with repose.

The train of symptoms makes the doctor think of grippe, pneumonia, typhoid, paratyphoid, rheumatism, or malaria.

Sometimes, in spite of the abatement of the fever and of the other disquieting symptoms, the patient seems to lose strength; he complains of continued pains in the lumbar region and legs and neuralgia all over; he complains of muscular asthenia and is without force or energy, to which may be added gastrointestinal atony, and his general condition may become neurasthenic.

There is no doubt but that the long resistance to mental and physical fatigue has so depleted the functional vitality in the subject that the waste products are imperfectly eliminated, and the patient's condition is aggravated by autointoxication which is probably the active agent in upsetting the thermic equilibrium, producing the fever of fatigue, the professional malady of the soldier.



A comparison of the symptoms and condition produced in these two classes of cases will cause the observer at once to note their similarity.

In the cases of trench fever described by the English and French authors, there are the same onset and train of symptoms as observed in army fatigue, with the addition of other signs of greater intensity, the former differing notably from the latter in the repeated accessions of the attack.

To those who have had experience with certain intense forms of malaria in the hot climates, the onset of trench fever by a chill, followed by fever of fairly defined and fixed duration, with the recession marked by profuse sweating; a renewal of these accidents after a given period of repose, which varies only slightly in duration; and the significant fact that the body lice taken from an affected subject will produce the clinical train in a healthy one, as well as the demonstration that the injection of the red blood corpuscles reproduces the malady and that the serum or plasma of the blood of the same patient does not, is fairly con-

vincing of the malarial nature of the malady. From my observation and knowledge and the observations of others on military fatigue, I am led to believe that trench fever is a manifestation of this morbid condition complicated and aggravated by malaria, which presumption would become a conviction if it is found that trench fever yields to treatment with quinine.

College Ambulance Units.—At the United States Army Ambulance Corps instruction camp at Allentown, Pa., there have been in training 4800 college men for service in France since June 8, and many of the units are now ready for service, showing the good results of intensive training. Dr. Van Voast, in charge of the Harvard section, has stated that the camp includes 135 units of thirty-five men each from colleges and universities extending from Yale, Harvard, Princeton, Amherst, Columbia, Pennsylvania and Fordham in the East, to Berkeley and the State of Washington in the West. These men will drive ambulances from the front line to the field hospitals. Each unit has been equipped with twenty-four Ford ambulances, one Packard truck, one Ford truck, one Ford touring car, and one motorcycle with side car.

Surgeons Still Needed for Army Medical Corps.—Surgeon-General Gorgas authorizes the statement that there remain vacancies for surgeons in the Medical Corps of the Army, both in the reserve corps and in the regular service. These vacancies should be filled soon in order that ample training in the duties of the military surgeon and sanitarian may be secured by the dectors desirous of these commissions. Physicians entering the reserve corps serve for the length of the war; those going into the regular service will fill a more permanent commission. Examinations for admission to the regular service are held on the first Monday of every month. Applicants for commissions should apply directly to Surgeon-General Gorgas, and will receive notification of the conditions and designation of the places for conducting examinations. Those desirous of entering the Medical Officers' Reserve Corps should apply to the nearest examining board.

Growth of Medical Work of National Defense Council.—The Council of National Defense, Medical Section, has been endeavoring to secure ophthalmologists for the army, and has been at work on the selection of an approved list of otologists. The research committee, under the direction of Dr. Vaughan, has opened up activities in different parts of the country for the perfection of various practical methods in the preparation of disinfectants for wounds, throat sprays used in the control of carriers of disease communicated by nose and throat secretions, etc. This work is not to be limited to war conditions only, but takes into consideration industrial conditions as well.

Plattsburg Soldiers Forbidden Vermont.—Colonel Wolf issued orders on July 19 forbidding any members of the Plattsburg garrison and training camp to visit the State of Vermont without the written permission of the commanding officer. Such order was issued on account of the presence of infantile paralysis in that State, more than seventy cases having been reported. As yet no cases of infantile paralysis have been reported on the New York side of Lake Champlain.

National Guardsmen in Good Physical Condition.—The work of examining the men of the National Guard going into the Federal service in the city armories in New York has been so thoroughly and quickly done that it is believed the work will be completed in a week, in marked contrast to the delay attendant on the same work at the time of the mobilization of the militia for the Mexican border. Headquarter officers consider it an even chance that the guard may be ready to leave for the Southern training camp by August 1. One of the features of the Federal examination is the small number of rejections for physical disabilities, less than 2 per cent., showing that the men had been subjected to a careful physical examination by the guard medical officers, and it is largely only those who have developed defects since being sworn into service who have been discharged for this reason. The men have been examined a company at a time, and when it is realized that at war strength a company may contain 175 men in it, the task of going over the entire guard of the city can be appreciated.

U. S. Doctors to the Front.—Coordination of America's medical service abroad with the Allies was discussed at a conference in Washington recently by Secretary Baker, prominent American physicians, and medical representatives of Great Britain and France. It is conceded that hundreds of additional American surgeons will soon be sent to France. Americans will continue as virtual heads of certain allied medical services at the French front.

Hospital Train Offered to United States.—The most modern and completely equipped hospital train ever built has been offered to the United States Government by the Western Maryland, Baltimore & Ohio, and Pennsylvania railroads, through the Maryland Defence Council. It will leave Baltimore for Washington, D. C., with several doctors and half a dozen nurses, the staff of the train, who will volunteer their services at the same time. The train consists of five cars containing an operating room, convalescent room, etc., and is well stocked with bandages and all other necessaries of a hospital.

Dr. Pearce Bailey of New York, chairman of the Committee on Furnishing Hospital Units for Nervous and Mental Disorders to the United States Government, a sub-committee of the National Committee for Mental Hygiene, has been invited by the Surgeon-General of the United States Army to accept a commission as major, serving as personal advisor to the Surgeon-General in all matters pertaining to psychiatry and neurology. Major Bailey is now on duty in the Surgeon-General's office. Dr. Frankwood E. Williams, associate medical director of the National Committee for Mental Hygiene, has been appointed vice-chairman of the committee and placed in charge of the work in New York.

RADIUM IN THE TREATMENT OF FIBROUS ANKYLOSIS.

NOTWITHSTANDING the many and great advances effected by orthopedic surgery during the past thirty years, even yet the best to be expected in the treatment of tuberculous arthritis, except when begun in the very earliest stages, is a stiff joint. This, while better than abscess and joint disintegration, is not a result in which the surgeon can take much pride, and various measures have been tried to restore motion. Bony ankylosis is, of course, practically hopeless, but fibrous adhesions continually tempt the orthopedist to renewed efforts to restore mobility. At one time thiosinamine was regarded hopefully, but the results of its employment did not come up to expectation. Forcible breaking up of the adhesions may restore motion temporarily, but the risk of lighting up the old trouble or of an even worse outcome is too great to warrant the undertaking in most cases.

Recently some encouraging experiments have been made with radium in this condition. The good results reported in the use of radium in mobilizing joints stiffened by arthritis deformans suggested to J. J. Nutt the employment of the same remedy in cases of fibrous ankylosis following tuberculous arthritis, and he reports in the *American Journal of Orthopedic Surgery*, No. 2, Vol. XV, six cases of ankylosis of the joints in which this mode of treatment was essayed. In most of the cases a radium pad was worn directly over the knee, radium solution containing two micrograms was given per os three times a day, and intravenous injections of radium element were given, the amount injected varying from 10 micrograms up to 50 or 100 micrograms, or one or more doses of 25 micrograms were given as conditions indicated. In the cases receiving the smaller amounts the injections were given about a week apart until the larger doses were reached when the time was extended to one to two months between injections. When the larger doses were employed but one or two injections about two months apart were given.

The process toward recovery was apparently definite but slow, as some of the cases were under treatment for over a year, although in one or two of the milder cases slight movement was obtained within about two weeks after the beginning of treatment.

The degree of motion obtained varied of course according to the amount of deformity and stiffness previously present. All of the patients were under continuous hospital care, and were made the subjects of routine hospital analyses as to blood, urine, etc. The Wassermann reaction was negative in each case. Nutt states that no general effect was noted besides that attributable to an excellent tonic; the patients themselves insisted that they felt better under the treatment. The results locally were more or less definite, even before any mobility was shown. A looseness was felt in the knee, more noticeable in the mornings than after use. When movement began to be perceptible, the knee assumed a slightly flexed position and offered a little difficulty in straightening, though this did not appear to be the same expression of muscular spasm as is met with in active knee-joint disease, but was rather an uncertainty of the muscles with regard to relaxation as motion increased. Heat or swelling was never present.

Since this is but a preliminary report, much is yet to be worked out before definite results as to permanency of cure or relief can be assured. As Nutt suggests, larger doses may hasten the process of recovery with perfect safety and other combinations of methods in administration of the radium may give quicker or surer results.

UNWISE PUBLICITY.

PICKING up recently the Sunday edition of one of the leading New York dailies, we saw the headline, "Says Doctors Fail in Tetanus." The article following occupied well over half a column. This seems to us to be an excellent example of unwise publicity in medical matters. Such a headline, published as it was in a leading metropolitan newspaper which has a large local and out-of-town circulation, was sure to attract the eye. The reader, glancing over the article, came across such statements as these: "Tetanus still prevails, chiefly because thousands of physicians do not avail themselves of tetanus antitoxin." "Tetanus is a preventable disease; why, then, this neglect on the part of the general practitioner? . . . It is an expensive remedy. And yet how inexpensive when measured against the value of a human life!" "Why is it that American physicians, supposed to be the most able and the most resourceful in the world, are so slow in taking up this experience and applying it in civil practice? Can any one answer? We confess it's too hard for us."

What is the inevitable result of such an article? Among the many readers of it will undoubtedly be

some who will have lockjaw, or know intimately persons who will have it; their physicians are, of course, discredited. Even aside from the actual occurrence of tetanus the profession as a whole is disparaged, and the impression given that the American practitioner remains behind the times, even at the cost of his patients' lives. It is no defense of such an article to say that it is quoted from a medical magazine. There are many matters of medicine about which a difference of opinion exists, many methods of therapeutic procedure are still *sub judice*, and the history of medicine is full of mistakes, false theories, and ignorance. But the display of these things to a lay public will be productive of more harm than good. The lay reader, untrained, as a rule, in scientific or judicial modes of thought, fails to bear in mind that the profession acts, on the whole, according to the best knowledge available, and that its individual members have ever the welfare of their patients at heart and conduct their treatments with this in view.

Referring to the actual point of issue—the universal use of tetanus antitoxin—we do not hesitate to say that it is not well taken. When we consider how many cases of lockjaw in civil life follow trivial injuries, perhaps a scratch or cut forgotten by the patient himself, and also how low the incidence of the disease is, we fail to see the grounds for the recommendation that tetanus antitoxin be administered in all cases of wounds. The physician who adopted this routine in his everyday practice would cause in the course of a year much needless inconvenience and pain to hundreds of patients, not to mention expense that they could perhaps ill afford.

The writer quoted gives in defense of his theory the experience of the armies in France, the high incidence of tetanus at first, and its spectacular decrease following the routine administration of prophylactic doses of antitoxin to all the wounded. Unfortunately, the analogy is not on all fours. The reason for the great prevalence of tetanus in Flanders has been stated over and over again in the medical journals of all the countries at war to have been the richly cultivated soil on which the battles were fought, soil fertilized for years by layers and layers of manure. Hardly a wound occurred which was not impregnated by this soil, an ideal breeding place for the tetanus bacillus. It would have been surprising, indeed, if there had not been a great deal of lockjaw.

It is quite generally conceded now that all wounds occurring in persons working about stables or in gardens, as well as wounds which are infected from the first or are inflicted by rusty weapons, should include in their treatment a prophylactic injection of antitoxin, but not that every man who happens to cut himself while shaving or every woman who runs a needle into her finger should be obliged to spend several dollars and submit to the pain of an injection.

It is doubly unfortunate, then, that such publicity should be given to advice with which so many authorities disagree, and which cannot but do harm. The question of public health is so important, especially now, when the nation is preparing for war, that the promulgation of risky theories or unjustifiable criticism of the profession, causing the public to lose faith in the source whence must come its aid, is greatly to be deplored.

ANOTHER VEXATIOUS LAW.

We called attention last week to a law passed by the New York Legislature, purporting to deal with traffic in habit-forming drugs, but actually treating only of opium and its derivatives; a law accomplishing no good purpose and only causing needless vexation to the physicians of the State. This law does no serious harm to anyone, but is merely fool-stuff. There is another law, however, passed by the same Legislature, which, if literally interpreted and enforced, will put an end to the practice of genitourinary surgery in this State. The law reads as follows:

Sec. 1142-a. *Advertisements relating to certain diseases prohibited.* Whoever publishes, delivers or distributes or causes to be published, delivered or distributed in any manner whatsoever an advertisement concerning a venereal disease, lost manhood, lost vitality, impotency, sexual weakness, seminal emissions, varicocele, self-abuse or excessive sexual indulgence and calling attention to a medicine, article, or preparation that may be used therefor or to a person or persons from whom or an office or place at which information, treatment, or advice relating to such disease, infirmity, habit or condition may be obtained, is guilty of a misdemeanor and upon conviction thereof shall be punished by imprisonment for not more than six months, or by a fine of not less than fifty dollars nor more than five hundred dollars, or by both such fine and imprisonment. This section, however, shall not apply to didactic or scientific treatises which do not advertise or call attention to any person or persons from whom or any office or place at which information, treatment, or advice may be obtained, nor shall it apply to advertisements or notices issued by an incorporated hospital or a licensed dispensary or by a municipal board or department of health or by the department of health of the State of New York.

Among other things this means that no medical journal can be circulated in this State, whether published here or not, which contains an advertisement of salvarsan or any of its substitutes, mercury, cubebs, santal, potassium iodide, or any other drug which may be used in the treatment of the disease mentioned, or of any suspensory bandage, catheter, sound, or other instrument which may be employed for such purpose. It would also forbid the distribution by mail or messenger of circulars or announcements of such medicines or instruments. It is a question whether, strictly interpreted, it might not also prevent the publication in a medical journal of any article on a genitourinary subject, published over the name of its author or containing the author's office address, since such articles would not then be embraced in the exception of any "didactic or scientific treatises which do not advertise or *call attention* to any person or persons from whom or any

office or place at which information, treatment, or advice may be obtained."

It is probable that the author of this law had the intention only of putting an end to the advertising of quacks in the lay press and by handbills, but a careful reading of the bill shows it to be much more far-reaching. It is really so obstructive to medical progress that we cannot understand how it was allowed to pass seemingly without comment or protest from the legislative committees of the State and county societies. The act goes into effect September 1.

ALCOHOLISM IN GRAND CANARY ISLAND.

Although the inhabitants of this well known isle have an excellent water supply and their famous native wine, they are noted for their abuse of spirits. They import annually 627,533 liters of distilled alcoholic beverages, 85,561 liters of alcohol and 22,290 liters of liqueurs. To these amounts should be added 2,851,200 liters of native wine, the total being equivalent to 570,886.8 liters of 100 per cent. alcohol consumed annually by the less than 150,000 inhabitants. These figures of Ramos in the *Gaceta Médica Catalana* for May 15 seem incomplete, as no mention is made of the amount of wine exported and no emphasis is laid on the amount of alcohol drunk by the floating population, chiefly "sailors from every port in the world," who start in on a spree the moment they land.

Ramos seeks to explain why natives of a warm climate, who should from analogy be wine drinkers, are so addicted to the use of spirits. A Canarian is famous for excuses to drink. He has his eye opener, his appetizer, his digester. He drinks when he is cold and when warm he drinks to be cool. Above all, he drinks because it is a universal custom. Ramos believes that the following factors are operative: First, the bad example of the sailors. Second, the monotony of the fare, for most people live on maize flour, milk, cured fish, and a few fresh vegetables. Aside from the fish they are practically vegetarians. Moreover, they greatly abuse spices and condiments, which abuse provokes thirst. Third, a certain monotony of life and the absence of certain kinds of amusements and diversions.

The effects of spirits consumption are shown in the records of the police courts, for 90 per cent. of those who come before them are, or were, "drunk and disorderly." Prostitution and syphilis flourish, as they have for centuries, and, computing the morbidity and degeneracy which result from spirits abuse, Ramos seems unaware that syphilis must play a rôle at least equal to that of alcohol.

The author has no remedies to suggest and only deplores a state of affairs which he perhaps believes to be irremediable. Despite the baneful effects of alcohol the Canarians are naturally loyal, men of their word, harmless, frugal, and charitable. It is a fact that no one has ever died of starvation on the island. Aside from offenses like adultery, for which alcohol is held largely responsible, Grand Canary has less crime than any other Spanish territory. The men are great sportsmen and athletes.

The Bacteriology of Icecream.

Icecream has been declaimed against on various grounds, principally, perhaps, on account of its frequently reported uncleanliness. There is no question, however, that icecream made under strictly hygienic conditions is, in addition to its grateful palatability, especially in hot weather, a nutritious food, and its use in certain complaints is of considerable value from the dietetic standpoint. The statement has been made that the distribution of bacteria in icecream is markedly uneven, that there is so great variability in the bacterial counts of different portions of the same container that any small sample selected for analysis will not represent the whole mass of the icecream. This statement is disputed by S. Henry Ayers and W. T. Johnson in Bulletin No. 503, U. S. Department of Agriculture, who give an account of the manner in which they determined bacteria in icecream. As a result of their investigations they came to the conclusion that the method of collecting samples and making bacterial counts used in the experiments gives results which indicate that bacteria in commercial cream are distributed quite evenly, and that an analysis of one sample from a gallon of icecream gives results which will hold for any other similar sample from the same gallon. Storage of icecream for eleven days in a commercial icecream cabinet, or in a hardening room for a period of two months, did not seem to cause an uneven distribution of bacteria. In a series of from five to ten samples taken directly from a large commercial freezer, the bacterial counts on each sample checked within the usual limits of error of bacterial analysis. No greater variation in bacterial counts between samples was observed when the plates were incubated at 37 deg. C. for 48 hours than when incubated at 30 deg. C. for a period of five days. When dilutions were such that about 200 colonies were present on the plates a lower variation between counts of samples of icecolonies per plate. The variation in plates made from the same sample was found to range from 7 to 26.6 per cent. Among duplicate plates a variation as high as 41 per cent. was observed.

The Baruch Public Bath.

On Tuesday of last week the Board of Aldermen of this city passed unanimously a resolution naming the Rivington Street baths after Dr. Simon Baruch. This is a well-deserved though tardy recognition of Dr. Baruch's labors during long years in establishing the system of free baths in this city. He began to agitate the question of free public baths in 1890, but met with so much opposition from the city officials and even the Board of Health that it was not until 1901 that the first public bath was opened at Rivington and Goerck Streets. Since that time several other bath houses have been built in other localities, and now the number of free baths given by the city is over 7,000,000 annually. It is a satisfaction to recall the fact that the Medical Record was always a firm supporter of Dr. Baruch in his fight for cleanliness and health.

News of the Week.

Tetanus Bacilli Spread by Germans.—W. B. Smith, Federal chemist, reports that court plaster, which is being sold throughout Kansas, is laden with tetanus bacilli. This report has caused the arrest of five Germans on orders of Fred Robertson, United States Attorney in Kansas City, Kan. The men posed as venders of court plaster, and when the farmers through the corn and wheat belts refused to buy, the plaster was given to them. Three Missouri chemists also verified the presence of the tetanus germs. Peddlers have also been reported selling imported plaster in New York and other States.

Enforcing the Dog Muzzling Law.—The Weekly Bulletin of the Department of Health, New York City, July 14, announces that 782 dog owners were summoned to court during the previous week for not muzzling their dogs and were fined a total of $1,211.

Paralysis Alarm in Vermont.—The Vermont State Board of Health has issued an order forbidding the holding of fairs, chautauquas, street carnivals, and circuses in that State until further notice, in an effort to check the spread of infantile paralysis. Sixty-eight cases have been reported this year, with six deaths; all but three cases were in Washington County.

Enlargement of Bellevue Hospital.—The growing demands of New York City, together with the demands arising as a result of America's entrance into the war, have necessitated an enlargement of the plant of Bellevue Hospital. The Board of Estimate is now arranging for the purchase of the block to the north of the hospital grounds, between Twenty-ninth and Thirtieth Streets, First Avenue and East River.

New Medical Plan Founded.—The National Social Unit Organization, which was created last year in New York City, has established a national social laboratory in Cincinnati, Ohio. A group of thirty-three Cincinnati physicians, living or practising within the Mohawk-Brighton district of Cincinnati, containing a population of 15,000 people, and comprising the social laboratory district, have organized as a group, have appointed an executive committee, and have elected a director for the purpose of conducting the health work of that neighborhood. These physicians serve as a local health department and the man whom they elect will serve as the health officer for the neighborhood. Clinics and classes in the prevention of disease will be established. Each physician will receive remuneration for the work he does; if the work thus performed interferes with private practice, an increased remuneration will be made. The necessary government of the social unit laboratory will be in the hands of these physicians. Dr. J. H. Landis, health officer of Cincinnati, president of the Cincinnati Academy of Medicine, is chairman of the committee which has developed this plan.

Birth Control Film Barred.—The Appellate Division of the Supreme Court has expressed disapproval of the exhibition of motion picture films dealing with birth control.

Women Medical Students at Columbia.—Announcement is made that a gift of $50,000 from George W. Brackenridge of San Antonio, Tex., will enable Columbia University to open its doors to women students this autumn. Work will be begun at once on the addition to the present building to provide extra laboratory facilities in the departments of chemistry, pharmacology, pathology, and bacteriology.

George Simmons has been appointed as messenger boy at $480 per annum in the office of the Chief of Naval Operations, Navy Department, and the *Official Bulletin* announces that the President permitted his appointment without reference to the civil service rules.

German Synthetic Drugs Banned.—Licenses under which German chemical firms have been exporting to the United States through northern European neutral countries serums, vaccines, antitoxins, and other biological products were formally revoked on July 21 by the Treasury Department. The order of revocation cites the inability of Treasury inspectors to inspect the plants of the companies because of the war. Seven of the chief chemical firms of Germany are involved.

Obituary Notes.—Dr. LUCIEN F. BACHELDER died at his home in Rockland, Me., on July 12, aged 81 years. He was a veteran of the Civil War, a member of the G. A. R., and also a licensed Methodist preacher.

Dr. EDWIN N. MAYBERRY, a graduate of the University of Vermont College of Medicine, Burlington, in 1882, died of apoplexy on July 14, at his home in South Weymouth, Mass., aged 60 years. He was a member of the Massachusetts State Medical Society, Norfolk Medical Association, and a fellow of the American Medical Association.

Dr. HARRY R. JOHNSON, a graduate of the University of Tennessee, Medical Department, Memphis, in 1887, and a practising physician of New Hope, Ala., died at Huntsville, Ala., on July 9, aged 55 years. He was a member of the Madison County Medical Society.

Dr. F. G. MARRERO, a graduate of Tulane University of Louisiana School of Medicine, New Orleans, in 1884, died on July 11, in the Presbyterian Hospital, New Orleans, from paralysis, aged 62 years. He was a resident of and had practised in Covington, St. Tammany Parish, La., of which town he was mayor for two terms and at one time coroner of St. Tammany Parish.

Dr. SAMUEL B. TOBEY, a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1860, and a pioneer physician of Pottawattamie County, Iowa, died in Omaha, Neb., from paralysis on July 8, aged 80 years. He was a veteran of the Civil War and a member of the G. A. R.

Dr. CHARLES B. JAMES, police surgeon of Denver, Col., died in St. Luke's Hospital, Denver, on July 8, from Bright's disease, aged 52 years. He was graduated from the Kentucky School of Medicine, Louisville, in the class of 1891, and for ten years served as county physician, previous to his later appointment.

Dr. EDWIN D. FARROW, a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1874, and for years county physician of Tulare County, Cal., died at his home in Visalia, Cal., on July 6.

Correspondence.

HOW TO EMPLOY THE PHARYNGEAL INSUFFLATION APPARATUS IN CASES OF EMERGENCY.

To the Editor of The Medical Record:

Sir:—I find that my article on "Resuscitation," published in the issue of the Medical Record for July 7, is too extensive to be of practical use for teaching of and learning by first-aid men how to employ "Meltzer's Pharyngeal Insufflation Apparatus" for artificial respiration in cases of emergency in man. I would ask you therefore to publish the following:

On finding an unconscious individual, without any, or with very insufficient respirations, employ immediately the apparatus (when at hand) in the following order:

1. Put the board on the abdomen (over the clothes) and compress it by the hand; the tightening of the belts can be finished later.

2. After examining mouth and throat for the presence of tobacco, false teeth, etc., pull out the tongue by means of the forceps (present in the hand bag) and insert the pharyngeal tube (the smooth side of the tube resting on the tongue) until it reaches the posterior wall of the pharynx; the tying of the tongue to the pharyngeal tube can be done later.

3. Start immediately working the bellows with one foot and moving the ring of the respiratory valve from right to left and from left to right (respiratory cycle) about twelve cycles per minute.

4. Start immediately to screw down the rubber tubing (which should be open at the beginning) attached to the T tube, while watching the chest for heaving (respirations); as soon as there is a definite heaving discontinue screwing the clamp screw. (In order that the screw should not fall off, it should be attached by means of a piece of cord to the metal T tube.)

5. Now tighten the board and tie the tongue (not too tight!) to the pharyngeal tube; the forceps may be then taken off. (If the respiration appears insufficient it is usually due to the falling back of the tongue; it should be pulled out again. If there is a steady tendency to fall back, either the tying should be made more tight or the tongue must be kept pulled out constantly by means of the forceps.)

6. After the respiration has been continued for about a minute turn the plate on the outside end of the pharyngeal tube and insert into the opening the stomach tube (present in the bag) and push it down into the stomach, or at least until it is noticed that air escapes from the external end of the tube. Throughout these manipulations the working of the bellows and of the respiratory valve should not be discontinued.

If several individuals are present, and willing to lend a hand, the very first act should be the attempt of resuscitation by means of the Sylvester method, while another person compresses the abdomen and tightens the belts for the abdominal board. As soon as this is done the Sylvester method should be discontinued and the pharyngeal tube inserted; the rest should be continued as outlined above. During the performance of artificial respiration other individuals may remove the clothing and various forms of stimulation may be applied; but the artificial respiration should under no circumstances be discontinued to allow of any other performances.

S. J. Meltzer, M.D.

13 West 121st Street, New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

COMPULSORY VS. VOLUNTARY TRAINING OF CRIPPLED SOLDIERS—REPORT ON THE MILK PROBLEM—INCOMPLETE MEDICAL EXAMINATIONS—ALLEGED UNFAIR TREATMENT IN REEXAMINATION OF EXEMPTED MEN—DEATHS OF MEDICAL MEN.

London, June 30, 1917.

Sir A. Boseawen, M. P., at a conference of stallholders and exhibition work by wounded soldiers, spoke of the value of voluntary work which is being done at various military and other hospitals, and said they were anxious to discover whether it is expedient or possible to introduce the compulsory system of training such as exists in France and Italy. There were many he said who refused to avail themselves of the opportunities given them, who were discharged from the army without training in a useful occupation, who had contracted habits of idleness when in hospital, and it was a difficult problem how to provide for them. Mr. Montague Barlow, M. P., presided and discussed the question from several points of view, the feeling generally expressed being adverse to compulsion. King Manuel, who has taken a personal interest in the working of orthopedic hospitals, mentioned that at the Shepherd's Bush Institution out of 1,100 patients 140 were undergoing training without compulsion. The employment of those men in the hospitals was a part of their treatment and had been most successful. Lord Charnwood said that in France it was found that very few men learn anything under compulsion. It was a plausible theory for quite young fellows, but applied to older men with wives and families it would be found they were dealing with very refractory material. An enormous amount of work could be done without using the word "must."

An interim report of the committee on the milk problem has been presented to the Houses of Parliament. It deals with the methods of encouraging and preserving supplies as well as with their distribution. The constitution of the committee is very representative, entitling it to speak on behalf of the great dairy interest in all parts of the country. It had to report upon production, conservation of supplies, to provide for the special needs of children in urban centers, organize supplies, and kindred subjects. To maintain the supply in time of war is recognized to be a complex problem. A shilling's worth of milk contains more nutriment than can be bought with the same money in the common cuts of meat or fish. Yet since the war began beef has risen in price 112 per cent., eggs 78 per cent., fish 138 per cent., and milk only 62 per cent. The price should be based on the cost of production. It is of importance to the dairy farmer to be able to obtain feeding stuffs, so full supplies of hay and roots must be secured. During May, June, and

July there is more milk available than the market can accommodate.

At the Law Society Military Tribunal, complaint has been raised of perfunctory examinations alleged to have been made, and one man was sent for reexamination as he was found to be epileptic. Formerly classified as B.1 he was found only fit for C.3. The chairman called it a great reflection on the Medical Board which examined the man in the first instance. He stated that a number of men had been passed for general service who had been altogether rejected when their cases had been reconsidered. It seemed that very rarely had men been thoroughly examined until the tribunal sent the case to the Medical Board. Then they received the examination which ought to have been given in the first instance.

Complaints have been made in the House of Commons of harsh and unfair treatment said to have been accorded in many cases by medical boards and recruiting officers to exempted men who have been called up for reexamination. The Government promised to appoint a committee to investigate the working of the act. This was approved by Mr. Asquith, who said there was overwhelming evidence that men whom no reasonable body ought to have dreamed of passing for any form of military service had frequently been passed in an almost reckless fashion. Mr. Bonar Law claimed that the War Office had tried to carry out its definite pledges and said he was not disposed to come before the House in a spirit of apology. He remarked that if when unpopular things had to be done members stimulated the unpopularity it would be impossible to bring the war to a satisfactory conclusion.

Dr. Edgar Browne (Phiz) died suddenly on the 22nd in his seventy-fifth year. Two years ago he celebrated his fifty years' membership of the Liverpool Medical Institution. He was president of the Dickens Fellowship and had written his father's life.

Deputy Surgeon-General C. J. Mansfield, M.D., M.V.O., R.N., died on May 7. He took the M.B., C.M., Aberdeen, in 1883, entered the navy in 1885, was fleet surgeon 1905-9, and deputy surgeon general 1914-16. He was created M.V.O. in 1909. He was a sportsman of wide sympathies, first-rate fisher, and enthusiastic boxer.

Lieutenant Charles Douglas White of the Flying Corps was killed on May 10. He had won the military cross, was gazetted lieutenant in the King's Rifle Corps in October, 1914.

Progress of Medical Science.

2. The Classification of Hay Fever Pollens from a Biological Standpoint. William Scheppegrell.
3. Some Notes on Artificial Pneumothorax. Paul H. Ringer.

3. Some Notes on Artificial Pneumothorax.—Paul H. Ringer states that he never injects more than 300 c.c. of gas at the first sitting (save when the gas is administered for stopping hemorrhage), no matter what the manometric readings may be, and at subsequent injections the gas is cut off when the water manometer shows a mean reading of zero, or, at most, plus one, or two cm. This conservatism necessitates a few more injections per patient, but the displacement of the thoracic contents comes about far more gradually, and subjective and objective signs of discomfort and oppression are less marked. In checking profuse hemorrhage these conditions must be disregarded as an emergency is to be handled. He has injected as much as 1000 c.c. at once to control bleeding. The brilliant results obtained from this method have impressed the writer with the importance of artificial pneumothorax as a hemostatic. Pleural effusions have responded in about 50 per cent. of Ringer's cases to this treatment, and it allows of more comfort to the patient. He removes promptly any considerable accumulation of fluid (any amount reaching to the fourth rib) and substitutes gas for it either at the time the fluid is withdrawn or shortly afterwards. Paracentesis is repeated if necessary, and the patient kept under fluoroscopic examinations in order to ascertain the condition of the fluid and the time of tapping. Air embolism is to be guarded against at the initial injection, as the needle may be pushed too far in and puncture the lung, tearing one of the vessels in the walls of the air alveoli, or going through the wall of a known or unsuspected cavity, with resulting air embolism. Avoidance or lessening of this danger may be procured first, by having the field of operation the highest point of the chest; thus, if the midaxillary region be chosen, a pillow or sand bag placed beneath the patient in such a manner as to make the field of operation convex, will serve the purpose; second, by inserting the needle very slowly and steadily through the chest wall until it is thought the pleura is reached, and by not inserting it at a greater depth than three or four cm., though in patients with very thick chest walls this latter rule must be disregarded. It is often possible to obtain only small pockets of gas varying in size from 50 to 200 c.c., and Ringer's experience has been that where typical pockets form it is useless to continue the injections in the hope that the pockets will coalesce and a collapse be obtained. In cases of partial collapse, symptoms of cough and expectoration will not wholly subside, a certain amount of absorption of toxic material will always take place, and gas injections must be indefinitely continued. The duration of collapse in such cases where a complete result has been obtained should be from eighteen to thirty-six months, preferably the latter, and Ringer is loath to advocate re-expansion under three years or more. He states that we may *think* healing has taken place; we do not *know*. Ringer takes the position of a conservative enthusiast with regard to artificial pneumothorax, save in those cases where gas is administered for the control of hemorrhage, when he becomes an unreserved enthusiast. He admits of no result in tuberculotherapy more brilliant than the change wrought by the successful induction of pneumothorax. The return to health and the subsidence of symptoms are sometimes so rapid as to be almost uncanny. However, on the other side of the picture we see few bluer and more despondent patients than those upon whom pneumothorax has been tried without success. They feel that the last straw has snapped, and in the vast number of cases they are right. Judgment and more judgment is needed in the selection of cases.

3. A Study of Thirty-seven Cases of Epidemic Cerebrospinal Meningitis.—Randle C. Rosenberger and David F. Bentley state that in this series of thirty-seven cases of epidemic cerebrospinal meningitis, observed during the latter part of February and during March and April of 1917, all the characteristic symptoms of the disease were present when the patients entered the Philadelphia General Hospital. Kernig's sign was pres-

ent in all cases, while the Babinski was present in the adults and only in a comparatively few of the children. Brudzinski's signs were also present in some cases; strabismus and pupillary changes were frequent, and in one case ptosis was observed. Herpes developed in four cases among the adults and only one was noticed in the children. In only four cases were rashes demonstrable, varying from a slight erythema to purpuric and ecchymotic spots. Cheyne-Stokes respiration developed in one case after a too rapid administration of serum, and "sportive delirium" was seen in two adults after a deep stupor. The fluid withdrawn varied in amount from ten to 400 c.c., depending upon the time the case was under observation and the number of punctures made. The diagnosis was made in every case from spreads when the fluid was first delivered to the laboratory. In most cases the organisms were few and the extracellular as well as intracellular characteristic Gram negative diplococci were found. After a dose of serum was administered, and, although the fluid was still turbid and polynuclear leucocytes were abundant, it was most difficult to demonstrate meningococci. In some instances cultures were made upon blood agar after a diagnosis was made in spreads from the initial fluid. In four fatal cases a nonhemolytic streptococcus was found in addition to the meningococcus, and in the one case of fracture of the skull pneumococci were present. Studies of cultures upon blood agar were made from the nasopharynx in thirty-five cases including patients, resident physicians, nurses and attendants. In only three was a Gram negative diplococcus corresponding to the meningococcus biologically and morphologically found. As soon as a bacteriological diagnosis was made injection of antimeningococcus serum was given. In some cases 15 c.c., but in most cases 20 to 30 c.c. were given as the initial dose. In some cases where the illness lasted over a week or ten days a total of 300 c.c. was given, and where these large amounts were administered from 300 to 435 c.c. of cerebrospinal fluid had been withdrawn. Following the administration of the serum headaches were common, cramps in the legs were almost constantly noticed, and in only one case was syncope present, and this followed the too rapid introduction of the serum. Forty adults were treated, of whom twenty-three were white and seventeen colored. In this group the mortality was approximately 55 per cent., fourteen white and eight colored. Eleven patients convalesced. The number of children treated from two months of age to eleven years was twenty-seven, of whom fifteen were white and twelve colored. In this group the mortality was 40.7 per cent., seven white and four colored. It is the belief of the writers that if these cases had been diagnosed earlier and the serum given immediately the mortality rate would have been decidedly reduced; also the meningococcus may have been of an extremely virulent type, as was proved by animal inoculation. A wise procedure would be also to give a dose of antimeningococcus serum in suspicious cases of meningitis where a cloudy cerebrospinal fluid is withdrawn upon puncture. Lumbar puncture should be made in all cases of suspicious meningitis.

3. Argyria Localis Due to Organic Silver Preparations.—George Manghill Olson states that a very unsightly permanent pigmentation of the skin may follow the local use of argyrol and the various other organic silver preparations. The use of freshly prepared solutions of argyrol does not diminish in any degree the danger of argyria; the bluish green or slate gray color is not due to a bluish green or slate gray color of the silver deposits, but to the fact that the dark brown silver deposits appear bluish green or slate gray when seen through the uninvolved translucent epidermis. The occurrence of localized argyria following the use of argyrol, protargol, etc., is uncommon, but the resulting blemish is so unsightly that every care should be taken in the use of these substances. The solutions should never be forcibly injected into any cavity or canal as the tear ducts, urethra, etc., and should not be applied when the skin or mucous membrane is not intact. The general opinion is that the condition is irremediable. Olson's conclusions warrant a more hopeful prognosis. Local measures, such as blistering and electrolysis, are possibly of some value in causing an inflammatory reaction that favors absorption of the silver deposits. The hexamethylenamine treatment should be given a trial in every case of argyria due to organic silver compounds. Hexamethylenamine used in local injections in 1:7,500 and 1:250 strength solutions may give striking results, as was obtained in the cases of two patients so afflicted, but Olson considers that it must be given more trial before definite conclusions can be reached.

1. A Lecture on the Treatment of War Wounds. Supplemented by Additional Matter Relating to Antisepsis and the Method of Carrel.—Almroth E. Wright discusses Carrel's procedure of intercalating between the complete dressings a frequent flushing and refreshing of the wound surface and for carrying out this flushing unlaboriously. He considers that by this method there has been made by far the most important contribution to surgical technique since the beginning of the war, and that while Carrel's procedure gives us a new and improved technique for the application of antiseptics, much more does it give us a new and improved technique for physiological treatment. Wright calls Carrel's method a "combined antiseptic and physiological treatment." Carrel's treatment is not in any sense a *therapia magna sterilisans*. Regarded as an antiseptic method, it is one of "*fractional sterilization*" requiring for certain types of cases at the rate of twelve douches a day, a series of sixty to 144 antiseptic douches in the given time for thorough treatment. There is, according to Wright, superadded to the antiseptic, a series of sixty to 144 physiological attacks upon the microbes, each such attack starting from an atryptic condition. While Carrel's work constitutes a very notable practical achievement, regarded as science it comes short in the respect that adequate control experiments are lacking. Wright states that he does not mean that it has not been demonstrated that Carrel's treatment accomplishes what was impossible by the old system of syringing with antiseptics and leaving the wound afterwards to fill with pus. The inefficiency of the old method was attested by tens and hundreds of thousands of control experiments. What he does mean is that there are not in Carrel's work any control experiments with more potent and penetrating antiseptics to negative the idea that with these one could with less than sixty to 144 consecutive douches convert a light surface infection into a negligible one. Again, we have not from Carrel any control experiments with a well-thought-out physi-

ological treatment to negative the idea that one could achieve a similar sterilization by sixty to 144 successive physiological attacks upon the microbes, starting each time from an atryptic condition. To remain in the spirit of science every unwarranted assumption must go. There must be no assumption that when we have successfully combated a surface infection by a series of sixty to 144 therapeutic operations finality has been reached. Much less must we, from the fact that a treatment successfully combats surface infections, infer that it is also an effective treatment for infections which penetrate into the deeper tissues. It ought to come home to us instead that we must never look to find for quite different categories of wound infections—*i.e.* for quite diverse conditions any one routine (antiseptic or physiological) treatment.

2. Bacteriology at the Front.—W. P. Herringham states that bacteriological investigation in hospitals of the front line has been a novel feature of this war. Nothing of the kind has been practised in any of the previous English campaigns, and it has been rendered possible by equipping motor vans as mobile laboratories. The first, which was sent out in October, 1914, had been a pleasure caravan, but it was fitted out to meet the needs of a laboratory. These vans have been attached to a clearing station or a group of clearing stations, and the officer in charge is provided with a small motor car, so that he can go to any place in his area where his services may be wanted. These officers perform three functions: (1) They examine all kinds of morbid products from the hospital wards, and thus aid in the diagnosis of enteric fevers and other epidemic diseases on the medical side, and of the various forms of infection that attack surgical wounds. (2) They examine contacts in cases of infectious fever and search for carriers both among the troops and in the civil population. (3) They investigate new forms of disease that appear among the troops in order to discover their causes and the means of prevention. Instances of the first-class methods of work are the examinations made of the blood and excreta in cases suspected of enteric fever, of malaria, or of dysentery, and of the cerebrospinal fluid, or the nasal mucus where cerebrospinal fever is in question. In the first year diagnosis of enteric at the front was comparatively easy; but, when, in January, 1916, the triple inoculation against typhoid and paratyphoid A and B came into use, difficulty was encountered. Firstly, the culture of the bacilli from the blood is very uncertain in inoculated patients after the first three days of fever, and, since the early symptoms are slight and are not distinguishable from those of many other fevers that prevail, few patients arrive at a clearing station within that time. Secondly, the triple inoculation so complicates the agglutination test that it is only after three or four trials and a comparison of the results that a conclusion can be reached. This takes twelve or fourteen days, so that it can only be carried out at the front in comparatively few cases that are retained in the infectious hospitals there, nor is it, even with the repeated examinations of the excreta in addition, always possible to obtain bacteriological evidence where the clinical symptoms render the diagnosis certain. In the case of cerebrospinal fever, Ellis, of the Canadian Mobile Field Laboratory, established at the same time as Mervyn Gordon at home the existence of different types of the meningococcus distinguishable by agglutination and absorption tests. During 1915 cases were observed in which, with acute symptoms just like those of cerebrospinal fever, the cerebrospinal fluid, though under high pressure, contained no polymorphs and no meningococci, but lymphocytes in excess. This condition was termed lymphocytic meningitis. It was never fatal. Later on several cases of meningococcal septicemia, which is a very acute and rapidly fatal disease, were discovered by the bacteriologists. Certain cases of dysentery occurred and were accompanied by a considerable amount of nondysenteric diarrhea. The next function of these officers is to discover the source of an infection and to stop it from spreading. In cases of enteric the work was very elaborate. In the first place a systematic search was made for recent or chronic carriers among the troops. In one regiment a carrier was discovered in the regimental kitchen; in another, which had lately received reinforcements, no less than ninety-six men had to be examined before the carrier was found. The source of infection was not always in the troops. The part of Flanders held by these particular troops was a hotbed of enteric, and many cases were found in the civil population. The search for these, in which the bacteriologists were aided by the Belgian sanitary officer, Dr. de Wulf, and also by the Society of Friends, was very difficult. In one village cases of enteric occurred in three successive formations that were billeted there. No civil cases could be traced until news was brought of a child that had been sent away to convalesce at a neighboring farm. The clue was followed and the family to which the child belonged were identified as the source of the outbreak. They kept an *estaminet* and sold food to the soldiers. Herringham also states that many carriers of dysentery have been discovered and isolated. The conditions of warfare make it harder to obtain contacts of cerebrospinal fever at the front where the men are moving, than at home where a man may be stationary for weeks. The subject is difficult and one method of diagnosis does not satisfy every bacteriologist; also, Herringham states that he cannot remember any instance in which they could connect two cases of the fever as cause and effect. As instances of the examination of new or little known forms of disease, he mentions trench fever, spirochetal fever, gas gangrene, and the histology of the prevalent nephritis.

La Riforma Medica.

June 9, 1917.

Case of Vagotony.—Pezzi describes a case of hypertonicity of the vagus in which the action of atropine was paradoxical. The case itself was of the type described by Laslette and by Wenckeback. There were subjective sensations (vertigo), accompanied by total arrest of the heart's action. When atropine was administered to offset this behavior it apparently set up new disorders—a ventricular automatism, with a false nodal rhythm and an inverted false rhythm. Slowing of the rhythm may follow the use of 1 mgm. atropine in certain normal subjects. This slowing is but one phase, as it is succeeded by a phase of acceleration, during which compression of the eyeball will cause a return of slowed rhythm. In some youthful subjects without cardiovascular symptoms an injection of atropine, irrespective of special dosage, promptly caused acceleration of the heart's action without preliminary slowing, extrasystoles or auriculoventricular dissociation. In attempting to explain this paradoxical action of atropine in some subjects in which the drug seems to "balk," it could be due in theory, at least, to too small a dose. Leaving out this possibility, the author says, this negative or inverse action of the drug should be dependent on the presence of certain organic or functional affections of the heart.

Etiology of Myasthenic Bulbar Paralysis.—In a recent number of the *Berliner klinische Wochenschrift* there is a report of two cases of this affection. One was due clearly to general bulbar myasthenic paralysis. The symptoms appeared at intervals, beginning with progressive weakness of the muscles of the lips and tongue and of the facial muscles. Then the muscles of the extremities and eyeballs were involved. The second case began as a Landry's paralysis, but this disappeared to return as ordinary bulbar myasthenic paralysis with ophthalmoplegias. It was learned that both these patients had had diphtheria and the same history can be found in similar cases. However, a survey of all the case material shows the operation of a great number of toxins, whether formed in acute disease, or through some perverse activity of the internal secretions or from exogenous sources (alcoholism).

Le Progrès Médical.

Autoserotherapy of Pleural and Ascitic Effusions.—Louis-Auguste states that this therapeutic resource goes back in history to 1894, when it was first used by Gilbert in a case of serofibrinous pleurisy. In France it was used at intervals without much enthusiasm, but in Russia Tschigayew became a partisan of the procedure (1904); while later (1909) Marcou published a series of favorable results. The present author studied the subject under the latter and made it the subject of his graduation thesis. He always found it difficult to get material from other clinicians. As a matter of fact, the earliest results were not encouraging. He has now a total of 20 cases, which may be summed up as follows: In certain instances, for one reason or another, treatment was not essayed until an advanced stage of the disease, in patients some of which had coincident lesions of the lungs, while some had been tapped unsuccessfully one or more times. The results here were not startlingly good, but the patients did recover in time. Irrespective of this series the majority of patients were not able to continue under treatment and some remained under care only long enough for the necessary injections. Nevertheless they did very well. The Marcou technique used by the author is as follows: An exploratory puncture is made in any suspected case, using Luer's 2 c.c. syringe. If a transparent citrine fluid comes away (the presence of blood is no contraindication) the author goes ahead with the procedure. He draws off from 5 to 10 c.c. of fluid and several days later injects it in one dose. Personally he has never used over 5 c.c. Subsequent injections may cause anaphylaxis. The reinjected serum causes a thermic reaction, rapid absorption of the exudate and abundant urination. Less constant are prostration and albuminuria. In pleuritic effusion it is, of course, possible for absorption to be spontaneous, but this is unlikely. The author has used the treatment in 2 cases of ascites with negative results, but when this condition is due to tuberculosis the reverse has been the case, although no data are given.

La Presse Médicale.

June 14, 1917.

Glycosurias of Renal Origin.—Roger states that the doctrine that glycosuria always presupposes hyperglycemia is a mere hypothesis. The discovery of phloridzin glycosuria showed that exceptions are possible. There are no less than 5 elements concerned in glycosuria. 1. The liver, which contains in its cells the sugar reserves. 2. The tissues which utilize the sugar (muscles). 3. Some of the organs of internal secretion (pancreas). 4. The nervous system. 5. The kidneys. Even the normal kidney is not a perfect barrier to the sugar in the blood. Even in very slight hyperglycemia a small quantity enters the urine, and in depancreatized dogs sugar appears freely in the urine when the sugar in the blood is not above 2 per 1000. A meal rich in starches, sugar, sweet wines, etc., may be followed by glycosuria in a perfectly normal subject. This matter has been tested in numerous people who have partaken of the same kinds of food, and in all but one out of eleven some alimentary glycosuria was present. Drinks alone in large quantities—wines, beer and cider—gave the same result. If the renal epithelium has normally the function of holding back sugar it is evident that in certain alterations of these bodies sugar may leak through, even with normal sugar content of the blood. A true renal glycosuria should not be influenced by diet and should occur in subjects free from hyperglycemia. The amount of sugar excreted should not be large. We know from studies on diabetics that there is no necessary parallelism between the per cent. of sugar in the blood and that in the urine. The kidneys seem to play a selective rôle. Animal experiments appear to show that the kidney accumulates sugar before its elimination. In other words, the kidney plays an active rôle in concentrating the sugar in the urine. Excretion is a two-stage process. In adrenalin glycosuria there is a notable disproportion between the degrees of glycemia and glycosuria, or rather a tendency to vary inversely. This form of glycosuria suggests a renal origin. It has been known for very many years that various salts of metals and also organic principles (cantharidin) are able to produce glycosuria along with polyuria. This type of affection is believed to be due to injury to the renal epithelium which affects the permeability. When the latter is evidently present addition of alimentary sugar will greatly increase the glycosuria, even in subjects with very low sugar content of blood (0.5 per 1,000). Clinically the number of well authenticated cases of renal diabetes on record is very small—not over 16. In nearly all of these there were no symptoms of functional character. In all such cases blood tests are necessary and it must be shown that hyperglycemia is absent. The sugar content of the blood fluctuates within normal limits and the degree of glycosuria must also be low in order to characterize cases as renal diabetes. In 13 cases the per cent. of sugar in the urine was 0.5 to 30 per 1,000. In regard to the nature of renal diabetes this cannot be surmised from the few cases on record. In one case heredity was apparent. In another there was evidently nephritis (albumin and red cells in the urine). In several cases especially tested general renal insufficiency was present, while there is also evidence of hepatic insufficiency. The number of hypotheses illustrates our lack of knowledge of the subject.

Correspondenz-Blatt für Schweizer Aerzte.

May 5, 1917.

Fat Embolism from Causes Other Than Fractures.—Katase edits the prevalent opinion that fat embolism is almost essentially a complication of severe fractures due to the absorption of liberated bone marrow by showing that it occurs after simple wounds of soft parts; further, that fat in the blood is by no means always held up in the pulmonary circulation. Again, fat emboli, even when present, are not necessarily the cause of death after severe accidents; and despite severe injuries to bones and joints fat embolism does not result because the marrow of the bones is found to be intact. In a case cited the source of the high degree of embolism must have been the subcutaneous tissue, for when the condyles of the femur and head of the tibia were sawed through there was absolutely no lesion discovered. Another question requires an answer—may not fat embolism occur without antecedent trauma? This may be answered in the affirmative as far as demonstrable wounds are concerned, but the definition of traumatism is not limited by size. Certainly in a small number of cases fat embolism occurs as a complication of parenchymatous nephritis, presumably when fatty degeneration is present. These cases, however, are complicated, because the circulatory system is not normal and again because a lesion of the lungs is a prerequisite. The arrest of fat in the lung capillaries occurs, therefore, under conditions very unlike those present in simple fracture of certain bones. In 111 miscellaneous autopsies of non-fracture cases 49 showed no evidence of fat emboli in the lungs and in 37 others there were only traces of fat present. If we add 18 others with small incidence of fat there remain but 7 cases in which fat was present in abundance. Of these "three and four plus" cases 5 presented some form of nephritis (4 parenchymatous, 1 atrophic unilateral). Four of the 5 presented lesions of the lungs. Miscellaneous complications included typhoid fever, icterus, diabetes, endocarditis, aortic degeneration, tuberculosis, etc. Of two patients without renal lesions one had pulmonary lesions and gastroenteritis hemorrhagica, the other miscellaneous internal hemorrhages. But in certain "controls" with similar complication of disease there were no fat emboli. This is also true of nine separate cases in which fracture was present. The subject is one of considerable forensic interest. In a death claim for damages for fall and fracture the presence of nephritis might cloud the responsibility and cut down the indemnity.

Carbuncle in the Palm of the Hand.—Gallois would hardly have ventured this diagnosis had not the patient presented an ordinary carbuncle on the back of his neck. Incision showed that a carbuncle, not a phlegmon, was the lesion. The center was excised and the lesion healed under glycerole of borated starch.—*La Presse Médicale.*

Book Reviews.

THE BIOLOGY OF TWINS (mammals). By HORATIO HACHETT NEWMAN. Price, $1.25 net. The University of Chicago Press, 1917.

Dr. NEWMAN is quite right that there is much in his book which will appeal to anyone who is a "twin or has personal acquaintance with a twin." The subject of twins is one which of itself arouses much interest. Though those not trained to scientific thinking will find the book very difficult reading in part, they will find it worth the necessary effort. The armadillo, being especially adapted for the study of twinning, has been the experimental animal in this study. The process of twinning is considered due to a "period of quiescence" of the fertilized ovum in the early stages, which allows the separation into distinct embryonic premordia. The question of sex determination is discussed, as twinning offers a special opportunity for the study of this subject.

In this connection the explanation of freemartins is given, that the male differentiating hormones develop earlier than the female and so the zygotic female, influenced by the male hormones, develops male characteristics. We are still at the beginning in an understanding of hormones and internal secretions, to which subject interesting light is thus added.

A TREATISE ON DISEASES OF THE SKIN. For Advanced Students and Practitioners. By HENRY W. STELWAGON, M.D., Ph.D., Professor of Dermatology in the Jefferson Medical College; Consultant to the Dermatological Department of the Philadelphia General Hospital, to the Pennsylvania Institution for the Deaf and Dumb, to the Pennsylvania Institution for Feeble-Minded Children, and to the Widener Memorial Training School for Crippled Children; Member of the American Dermatological Association; Honorary Member of the Society of Dermatology and Syphilography of Italy; Associate Member of the Society of Dermatology and Syphilography of France, of the Vienna Dermatological Society and of the Berlin Dermatological Society. Eighth Edition, Revised. With 356 text illustrations and 33 colored and half-tone plates. Price, $6.50. Philadelphia and London: W. B. Saunders Company, 1916.

LITTLE need to be said concerning Dr. Stelwagon's work on diseases of the skin. It is an old favorite. The present edition contains new articles on occupational dermatoses, paraffinoid, purpura annularis telangiectodes, xanthoma elasticum, and ulerythema ophryogenes, while the articles on pellagra, angioma serpiginosum, erythema elevatum diutinum, pemphigus neonatorum, leprosy, the leucemias, eczematoid ringworm, and coccidioidal granuloma have undergone revision, elaboration, and alteration. Thirty-eight new cuts have been added. The book is excellent throughout and supplies a very valuable reference book on diseases and affections of the skin.

A PRACTICAL TREATISE ON FRACTURES AND DISLOCATIONS. By LEWIS A. STIMSON, B.A., M.D., LL.D. (Yalen). Professor of Surgery in Cornell University Medical College, New York; Consulting Surgeon to New York and Bellevue Hospitals; Corresponding Member of the Société de Chirurgie of Paris. Eighth Edition, Revised and Enlarged. Octavo of 946 pages, with 475 illustrations and 39 plates in monotint. Price, cloth, $6.00 net. New York and Philadelphia: Lea & Febiger, 1917.

THE present edition of this work has evidently undergone a real revision and not merely a revamping by the addition or substitution of a few words or phrases here and there. Particular attention has been paid to the description of new methods of treatment and to a more definite evaluation of methods that were *sub judice* when the previous edition was written. In the course of two visits to France during the present war the author was enabled to review the work being done in many war hospitals and form a first hand opinion as to the value of the newer methods called into existence or elaborated through the exigencies of war surgery. According to their importance these are fully or briefly discussed—approved or severely criticised with an air of impartial justice—hence Stimson's treatise assumes added importance now that during the next few months our own surgeons will be preparing themselves for work with the United States forces abroad. The devices for the suspension treatment of fractures that have been most useful by Blake and by the various surgeons attached to the American Ambulance are described and illustrated; and the same may be said for the Steinmann nail extension and other methods that have recently been accepted as available in suitable cases.

It is to be regretted that the initial statistical chapter had not been revised. We still find the statistics of the Hudson Street Hospital for the ten year period 1896-1905, during which time 14,566 fractures and 1,527 dislocations were treated. It would seem that the opportunity should have been taken to add the statistics to 1915, thus doubling the period of record. The one portion of Stimson's book that always has been and still is exasperatingly bad is—*the index*. It should be elaborated to at least twice its present length and the fracture and dislocation indices combined. This is primarily a book for reference rather than for consecutive reading; hence the index should be particularly comprehensive.

DR. LYMAN SPALDING. The Originator of the United States Pharmacopœia. Co-laborer with Dr. Nathan Smith in the founding of the Dartmouth Medical School and its first chemical lecturer; President and Professor of Anatomy and Surgery of the College of Physicians and Surgeons of the Western District, at Fairfield, N. Y. By his grandson, Dr. JAMES ALFRED SPALDING. Price, $3.50. Boston: W. M. Leonard, 1916.

BIBLIOGRAPHIES seem to hold a peculiar fascination for members of the medical profession, possibly because they depict the struggles and victories and hint at the failures of the men and women who have faced life along the same path, thus bringing intimate experience of the peculiar difficulties encountered and means taken to meet them to others in a broad, altruistic way. Whether we admit it or not, physicians are among the lone souls of the world. They are compelled to be, else how could they dare to attempt to bear the burdens, solve the problems, sympathize with or correct the mistakes of the thousands of suffering humans who turn to them for understanding or relief?

Rarely does one physician turn to another for the solving of his problems. He stands alone, each the center of his own world, wielding influence according to the type of mind and spirit he possesses. In the loneliness of his work, in the weariness of the hour, in the happiness of result well accomplished, he so often finds the consoling power, the intimate touch, the encouragement and faith in a biography which offers that needed insight and broad outlook physicians are timid of seeking in their brothers. This reluctance to demand is one of the finest attributes of a busy practitioner, for it means recognition of the other's needed limitations to give.

This biography of Dr. Spalding justifies its existence in every way. It is well written, well published and recalls the days when one man had the power of tremendous influence on the thought and work of his time. That time is fast disappearing, for the day has come when conservation of men and energy—group work—brings to bear the influences to be welded in a large way for large results. Does it mean that the future will hold fewer biographies? That the individual effort will be engulfed in the larger attainments of units of men and women compelled to strive faster *en masse* by the force of the world's drive?

COLLECTED REPRINTS FROM THE GEORGE WILLIAMS HOOPER FOUNDATION FOR MEDICAL RESEARCH. The Department of Research Medicine of the University of California Medical School, San Francisco. Volume I, 1915-1916.

THIS interesting group of papers is the first from the George Williams Hooper Foundation. All the papers have been published before and hence are not new to those who will be most interested. The work on proteose intoxication and bile pigment metabolism is especially well known and appreciated.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-second Annual Meeting, Held in Atlantic City, May 2 and 3, 1917.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. GEORGE DOCK OF ST. LOUIS, IN THE CHAIR.

(*Concluded from page 42.*)

Thursday, May 31—Second Day.

Election of Officers: *President*, Dr. Francis Henry Williams of Boston; *Vice-President*, Dr. John H. McPhedran of Toronto, Ont.; *Secretary*, Dr. Thomas McCrae of Philadelphia; *Recorder*, Dr. Thomas R. Boggs of Baltimore; *Treasurer*, Dr. James Almarin Capps of Chicago; *Councillor*, Dr. Theodore C. Janeway of Baltimore; *Representative on the Executive Committee of the Congress of American Physicians and Surgeons*, Dr. Richard P. Strong of Manila, P. I.; *Alternate Representative*, Dr. Francis Weld Peabody of Cambridge, Mass.

The Occurrence of Bilirubin in the Plasma and Other Body Fuids.—Dr. M. A. BLANKENHORN and Dr. C. F. HOOVER of Cleveland presented this paper, which was read by Dr. Blankenhorn. Four hundred specimens of blood plasma, or thereabouts, obtained free from hemolysis were examined for bilirubin, bile salts, urobilin, and a fewer number of cholesterin. These findings were correlated with an examination of the urine and the appearance of the skin. The presence of pigments other than bilirubin was anticipated and all pigmented plasma were investigated by several tests. In particular Gmelin's test was compared with the Huppert-Cole test. The dialysis through collodion membranes into water, of bilirubin, bile salts, urobilin, and cholesterin, was observed. The specimens were taken from jaundiced patients, patients suspected of jaundice, and many apparently normal. The largest groups studied were those patients with obstruction, cirrhosis, pneumonia, and the anemias. Of 222 cases, 140 were jaundiced, 82 not jaundiced. In 153 cases there was cholemia without choluria. Bile salts were found in the urine in 102 instances. In 133 cases examined for urobilin in the blood, 22 were positive, and urobilin was present in large amounts. Oftentimes they found urobilin in the urine and not in the blood. In Laënnec's disease of the liver there was cholemia without choluria. Cholelithiasis was not demonstrable.

Cases Illustrating the Causation and Curability of Certain Long-Standing Albuminurias.—Dr. DAVID RIESMAN of Philadelphia related some of these cases. Cases of long-standing albuminurias should not be considered as incurable. Albuminuria might be kept up by the presence of stone or some offending foci. When patients were cured of such albuminurias they usually continued to live for years.

Dr. THEODORE C. JANEWAY of Baltimore said that when this condition was first recognized in the earlier days as being associated with Bright's disease, the patients were usually condemned with the diagnosis and prognosis of Bright's disease. In the historical development of albuminuria he said that in 1870, which was forty years after Bright's original article, people awoke to the fact that because a patient had albuminuria did not signify that the kidneys were radically diseased. Finally, it became recognized that postural albuminuria existed and that posture was one of the most significant causes of the albuminuria. Orthostatic albuminuria was an incorrect term; it was often difficult to say whether postural albuminuria was the only condition present. It was stated that many cases when placed in bed for three-quarters of an hour had their albuminurias clear up. This was a mistake, because the kidneys could not recover with such rapidity. Another matter that was tested in regard to simple posture—if the patients ran around they did not get albuminuria, but if they stood still they did get albuminuria. Dr. Janeway recalled a case of renal stone in a patient who always had albumen and hyaline casts in the urine. The radiograph showed the presence of stone. With the removal of the stone there was a disappearance of the casts and albumen. He recalled another case of interest. This man was refused by a life insurance company because of showers. He took up boxing, and later albumen and casts appeared in the urine. Dr. Janeway saw this case thirty years after his father had made this discovery.

Dr. WILLIAM S. THAYER of Baltimore recalled one case of a patient, fourteen or fifteen years of age, who had been brought to him with the suggestion that a warm climate was best for him. He had an infection from adenoids and from the tonsils. Tonsillectomy, together with the removal of the adenoids, caused the symptoms to disappear. Albuminuria often followed the use of cold baths, taken in the early morning.

Dr. LEONARD G. ROUNTREE of Baltimore recalled the case of a man who was perfectly normal except for a renal invasion; there were no signs of nephritis except the presence of albumen and a few casts. He had had tonsils. There had been a tremendous improvement since the diseased tonsil was treated. Sometimes simply the removal of foci of infection from the tonsils and adenoids would relieve the patients of albuminuria.

Dr. MILTON HOWARD FUSSELL of Philadelphia said that one great difficulty when there was found foci of infection in the teeth was in deciding just what to do and what kind of treatment should be employed.

Dr. WILLIAM S. THAYER of Baltimore said that dentistry was an important part of surgery, and dentists should be present at their meetings.

Elimination of Uric Acid in Gout and Other Forms of Arthritis.—Dr. JOS. H. PRATT and Dr. C. W. MCCLURE of Boston presented this paper which was read by Dr. Pratt. They concluded that the retention and delayed excretion of uric acid occurred in other diseases as well as in gout. Hence a retarded and diminished excretion of uric acid was probably not an essential factor in the production of gout. Injected uric acid remained in the blood of gouty patients longer than in the blood of nongouty. Some impairment of renal function was found in all the cases of gout studied by the newer methods.

Dr. LEWELLYS FRANKLIN BARKER of Baltimore said that the observations made were very important and wished to corroborate the statement made regarding the difficult of diagnosing gout in the absence of tophi. The majority of the cases that were diagnosed as gout at the spas were not gouty cases at all, but an infectious arthritis or an osteo-arthritis. The diagnosis of gout without the presence of tophi was very unsatisfactory. The unreliability of the methods of studying uric acid must be emphasized. He thought the evidences favored the view that in gout renal insufficiency was at fault as regarded the excretion of uric acid.

Dr. ABRAHAM JACOBI of New York said that he knew the diagnosis of gout was made when large quantities of uric acid were found in the urine. When there was no uric acid it still was diagnosed as gout because it was concealed and did not come to the surface. He supposed that in the next year or two more papers would appear on the diagnosis of gout.

Dr. JOS. H. PRATT of Boston, in speaking of the endogenous output, said that if the diet was purin free the uric acid was low. He thought it very important to make observations on young individuals.

A Consideration of Calcium and Magnesium in the Blood in Rickets and Tetany.—Dr. JOHN HOWLAND and Dr. WM. MCKIM MARRIOT of Baltimore presented this study which was made by Dr. Howland. He said the object of the paper was to determine the calcium content in the blood in rickets, but they also investigated the calcium content and its close relationship to tetany. They also obtained evidences of a therapeutic procedure in tetany. The calcium was expressed in mgs. per 100 c.c. of serum. The normal was about 10 mgs. In both classes of cases the tendency was for a low calcium content, lower in the severe cases that in the mild, the lowest being 7.5 mgs. There was a diminution of the calcium content in rickets. The relation between tetany and rickets was close. The cases of tetany varied in its severity and it might be low in calcium as determined by the galvanic current. In fourteen out of fifteen cases there were repeated convulsions, and when the convulsions occurred there were 6 mgs. of calcium in the

serum. It seemed, therefore, that calcium was a therapeutic method in the treatment of tetany, but he did not know whether it was of real value or not. However, in six cases in which it was used it seemed to be of great value and no child had had any convulsions after its use.

Dr. SAMUEL J. MELTZER of New York asked if in those cases where the calcium was diminished the amount of magnesium was determined. A most striking experiment was told in which there was a reduction of the calcium in animals by the use of oxylates; if magnesium was then added the animal became completely paralyzed. Then when calcium was given the animal awakened quickly.

Dr. LOUIS B. WILSON of Rochester, Minn., asked if they had determined the ammonia compounds in the blood.

Dr. JOHN HOWLAND of Baltimore said they had not determined the ammonia content in the blood. The consideration of magnesium in the blood would be considered at some future time, but so far they had found the magnesium was not much altered.

The Influence of Pituitrin Upon the Urinary Excretion in Diabetes Insipidus.—Dr. LEWELLYS FRANKLIN BARKER and Dr. HERMAN O. MOSENTHAL of Baltimore presented this paper which was read by Dr. Barker. He reported the case of a patient recently observed suffering from diabetes insipidus in whom by the use of pituitrin the urinary output could be reduced from 8 to 10 liters in the twenty-four hours to a normal output and the specific gravity correspondingly increased. Experiments on the most suitable dosage of pituitrin would be reported and also the effects of other remedies. The patient's response to pituitrin corresponded fairly close to that of a few other patients that had been reported in the foreign literature.

Dr. HERMAN O. MOSENTHAL of Baltimore said that the effect of each injection was marked for about four hours. Single injections, though the dose be large, had little effect. Apparently the dose must be repeated and two injections given. Then the effects were much more pronounced than they were with the first injection. The minimal dose was 1 c.c. and more numerous injections than two were really of no advantage. These conclusions bore out the conclusions of others.

Dr. JAMES A. MILLER of New York said that pituitrin in normal or diseased individuals caused a reduction in the urinary output. They gave a man intravenous injections of 0.5 c.c. of pituitrin, which was followed by a terrific headache, but it was the first time in eight years that he had not been compelled to rise at night to urinate. Intramuscular injections were given without effect. It was the posterior lobe that was effective in these cases.

Dr. THOMAS B. FUTCHER of Baltimore said a point that should be emphasized, which was based upon observations made today as well as those made by others since Frank described in 1912 the case of a man who had been shot with injury to the pituitary fissure and died of diabetes, was that injury to this gland might result in diabetes insipidus. The theory that diabetes insipidus was the result of the inability of the kidneys to concentrate the urine held sway for some time. Later the true etiology of the disease became evident. Investigations showed that pituitrin increased the output of the urine and the specific gravity and the ability of the urine to concentrate salt and nitrogen. Cushing's observations on tumors of the pituitary gland were of interest. In 12 out of 100 cases of pituitary tumor there was an increased flow of urine. Many of these cases had a marked polyuria, and six came to necropsy with the diagnosis of diabetes insipidus. Lack of time prevented him from attempts to explain the pituitary theory of the causation of diabetes insipidus and the associated cases with hereditary influences.

Dr. S. SOLIS COHEN of Philadelphia reported two cases of diabetes insipidus. One was a man 30 years old, a master mechanic at Altoona. In addition to passing large quantities of urine he complained of severe pain in the left hypochondrium. The giving of pituitrin caused the urine to clear up, but the pain continued. There was found an adhesion between the colon and the stomach, the cause of which was not evident. These adhesions were liberated and the urinary output fell from 11 or 12 liters to 2 liters. The other case was a girl 18 or 19 years of age. Her father died of tuberculosis and a sister had exophthalmic goiter, endocrine, and other disturbances. The urinary output was 8 liters a day, and after the administration of pituitrin it fell to 2 liters a day.

Dr. HENRY KOPLIK of New York said that he had been able to collect three cases so far and it seemed to him that it was difficult to separate the two classes of cases. This new therapy might be applied to a certain set of cases.

Dr. JOHN H. MCPHEDRAN of Toronto, Ont., said that polydypsia or polyuria had been spoken of—Was polyuria the general cause of the condition? He referred to a man who was markedly emaciated and who died two days after he first saw him. The question arose, If the disease was organic should the treatment be continued?

Dr. LEWELLYS FRANKLIN BARKER of Baltimore said that the observations of the Mayos were true, that was, there was an inability of the kidneys in certain cases to excrete urine without some form of therapy. If they administered pituitrin this inability was overcome. With regard to the hereditary cases there was something at fault and the pars intermedia seemed to be the actual site of the disease in diabetes insipidus. In cases in which the posterior lobe was destroyed substitution therapy must be carried out so long as the patient lived. Disease of the pars intermedia or the posterior lobe of the pituitary gland might be the cause of diabetes insipidus.

Dr. HERMAN O. MOSENTHAL of Baltimore said that certain studies were not attempted because the patients were so nervous. In the literature some observations were made on the blood and it was in all the cases practically normal.

Report of a Case of "Wilson's Disease," with Post-Mortem Findings. — Drs. CAMPBELL PALMER HOWARD and C. E. ROYCE of Iowa City, Iowa, presented this communication, which was read by Dr. Royce. The patient denied the use of alcohol and said he had never had any infectious disease, but that he was liable to attacks of diarrhea. He was bright, good natured, and from a successful family. In 1916 he had pains in the legs and some difficulty in his gait. He shuffled his feet. He had edema of the legs. For three or four weeks the symptoms persisted. Four weeks after the onset, in December, he had cramps in the legs, hands, and feet, especially the toes of the right foot. He became more ataxic and quite emotional. He suffered so that he was sent to the hospital. He was very sick and complained of severe pains during the examination. The fingers were flexed on the hands, the wrist was flexed on the forearm, and the arm was extended and held closely to the side. The thighs were flexed on the abdomen, the feet were extended and the toes were flexed. They first thought they were dealing with a case of tetany, but there was no mechanical or electric irritability at this or at subsequent examinations. The skin was harsh and dry and the lower extremities were edematous. The hair was scanty. The abdomen was tympanitic. The urine and the blood counts were normal. Careful and repeated examinations of the central nervous system revealed nothing unusual in the motor or sensory tracts. No diagnosis was made by them at this time. The spinal fluid was examined and no cells or Noguchi or Wassermann were determined. The calcium content was unusually high, 13 mg. per 100. There was no dysphasia and no dysarthria. Later the patient had some signs of fever. No organism could be found in the blood. He died with symptoms of a terminal infection, a basal infection. When the abdomen was opened they received quite a shock. The liver was very nodular and studded with large white nodules and suggested an adenocarcinoma or a tumor of similar nature. The nerve tissue was held for examination. They had carefully searched the literature in order to obtain aid in making a diagnosis of this peculiar condition, and found that in 1912 Wilson had described a new symptom complex. He collected four cases of his own and six in the literature and described the clinical phenomena; their case was similar to those described by Wilson. Since Wilson's paper there had been nine such cases collected in this country. It was of special interest that the symptoms of a condition called pseudocirrhosis were identical with Wilson's

syndrome. The pigment was tested for silver and manganese, but no chemist had been able to determine just what discoloration of the skin was caused by. In Wilson's disease they might get all grades of discoloration.

Dr. J. Ramsay Hunt of New York said they had some lesions in mind that were circumscribed and confined to the caudate, the lenticular nucleus, and to the corpus striatum. The tremor resembled that of paralysis agitans, but there was also a tendency to a clonic spasm and choreiform movements. Wilson emphasized the importance of this tremor. Gowers first described it as tetanus. One week ago in a study of juvenile paralysis agitans he found the lesion was situated in the corpus striati and limited to the larger motor cells. Paralysis agitans was a type of disease due to atrophic disturbances in the large motor cells. Huntington's chorea was a type of destruction of the smaller cells. The massive lesion in Wilson's disease was a combination of the destruction of the two systems.

Dr. Lewellys Franklin Barker of Baltimore said that this was the first case ever presented before this Association. There were two or three things that might be confounded with this disease. The remarks made regarding "cheese brain," that the brain looked like a slice of Swiss cheese, might be explained by the presence of the gas bacillus after death.

Dr. Royce, in closing, said that the hilus in the base of the brain was not at all pathognomonic of Wilson's disease. So far as he knew there was no case of pseudocirrhosis or Wilson's disease ever exposed to manganese. There were some evidences of a symptom-complex in which the manganese marked a somewhat similar type as the disease under consideration.

The Use of Foreign Protein.—Dr. James L. Miller of Chicago presented this communication in which he reported his experience with the administration of foreign proteins in various conditions besides typhoid fever. The reports of the treatment were rather uniform. Patients who had iritis, for example, showed evidence that something had happened after receiving this treatment. Abroad arthritides of the gonorrheal type had been studied; the speaker also had been treating the arthritides by this method. In iritis, in addition to the protein, they used collargol; the patients invariably had a chill for thirty minutes, which was followed by a profuse sweat. The leucocytosis appearing in from six to twelve hours required from twenty-four to forty-eight hours to return to normal. With a modification of the procedure, it was found that there was a definite rise in the blood pressure; at the end of six hours another chill occurred, and then there was a drop in the blood pressure. The systolic and diastolic pressures paralleled each other throughout the entire procedure. Not infrequently there was vomiting or nausea, with headache. Herpes often occurred and developed as a severe reaction. Typhoid vaccines, 100,000,000, were given intravenously. The patients, as a rule, said they felt better after the sweat. During December and January thirteen cases required a second injection. Not all would clear up after the single injection. In some cases the symptoms cleared up, but soon recurred. As a rule, the recurrences were slight. After the second or third injection the patients were, as a rule, free of their symptoms. During March and April they discharged from the hospital fourteen patients who had had acute arthritis; in this group the patients received one injection every day until three had been given; among these fourteen there was only one recurrence. This patient was taken to the hospital not improved. They used the typhoid vaccines. They got no beneficial results from the use of the gonorrheal vaccines, yet they did get them from the use of the typhoid vaccines. In the subacute or chronic cases the results were less marked. They had used them in eight or nine cases of pneumonia and the reactions were quite violent. One patient had a temperature of 109.2°, which dropped to 97° and then went up to 103°, dropping again to about 100° and remaining there until the normal time of crisis. They had treated more than 200 cases and given more than 500 injections and they had not had a fatality. If one was careful in the administering of this agent there should be no bad results. After using this treatment for one and a half years it had given them more marked results than any other treatment employed. They had always looked upon the temperature reactions as being essential to the patient's recovery.

Dr. Ernest Edward Irons of Chicago said that in considering the possible nonspecific elements in the phenomena of disease, it was not proposed to supplant the older ideas of specificity, but to discover in what ways these non-specific reactions helped or hindered the specific factors, or acted independently of them. Studies of the changes brought about in the animal body by the introduction of foreign protein had not only developed new conceptions, such as those of the mobilization of serum proteose and the relation of normal ferment and antiferment, which seemed destined to throw light upon a number of unexplained phenomena of disease, but had also broadened their views in regard to the older theories of the more specific factors. In this discussion of the effects of foreign protein in disease their interest centered in two main topics: (1) The relation of the phenomena observed to those which occurred in the natural recovery from disease, (2) the clinical results which followed the use of foreign protein in disease.

1.—Specificity in biological reactions had been the guiding principle of those who had attempted to devise methods of study and therapy of infectious diseases, and while modifications in the original theory of antigen and antibody had from time to time been found necessary, it was along this line that most of the progress to within the past two or three years had been made. While the reactions which they spoke of as specific differed from those they called non-specific, in the conditions and methods of demonstration, they might conceive of both classes as dependent on physicochemical principles, differing only in the degree of fineness of their adjustment. The findings of Hektoen indicated that in carefully controlled animals, the introduction of one antigenetic substance might cause the appearance not only of antibodies specific to the recently injected antigen, but also antibodies specific to another different antigen, in an animal previously sensitized to this later antigen. Bacterial antigens in suitably prepared rabbits had been found by Conradi and Bieling to produce like results. The recognition of this interrelation of specific and nonspecific reactions was an important step in understanding the problem of the effects of foreign protein in infections, and of the effect of one infection upon another in the human body.

2—To what extent did results warrant the use of intravenous injections of foreign protein in infections, especially typhoid fever and arthritis? The published reports had led to a widespread employment of the procedure, especially in arthritis, often by those untrained and uncritical in judgment. In typhoid fever a number of favorable reports had appeared. On the basis of their own observations and those of others they had not felt justified in further extending their use in this procedure in typhoid fever. In patients suffering from arthritis, very striking amelioration of pain and swelling in joints had been noted following the reaction by the intravenous injection of bacterial or other foreign protein. There was always the danger that the routine use of a nonspecific remedy might lead to the incomplete or careless study of patients. In addition to weighing the successes and failures in the alleviation of the symptoms of disease, they must take into consideration also the other effects of the injection upon patients. It was perhaps difficult to estimate the probable remote effects of the introduction of foreign protein and the attendant shock upon the kidneys and other organs, though there was some evidence that such unfavorable effects were produced. He referred to three instances in one hospital within six months in which patients died following intravenous injections of bacterial protein. The study of the nonspecific elements in disease was of great importance and promised to open for them new avenues of attack. From a therapeutic point of view, however, he believed they should warn against the indiscriminate and routine use of these methods until they had been more thoroughly studied and the dangers as well as the reputed advantages better defined.

Dr. S. Solis Cohen of Philadelphia said that some years ago a certain manufacturing firm introduced a

substance supposed to be toxic filtrates, and he had some experiences with that product. Fortunately, he had no deaths, but he had several frights that warned him against any further use of this substance. In some cases of pneumonia happily they recovered, but by more violent reactions than he expected, and he made up his mind that this line of treatment should not be pursued further. He had, however, used colloidal silver and gold and obtained satisfactory results in cases of profound sepsis and the toxemias of various origin, especially in streptococcus infections. In no instance did he have any violent reactions. In regard to the treatment of arthritis by intravenous injections he referred to the use of formalin; in almost every instance there was an immediate disappearance of the pain. When the patient recovered it was prompt and continuous and there were no relapses and no violent reactions.

Dr. Milton Howard Fussell of Philadelphia said that it seemed to him from what they had heard from Dr. Miller that if the Association allowed itself to recommend the use of the intravenous injection of foreign protein in various types of disease it might do a great deal of harm. He believed that the remarks of Dr. Irons should be in the hands of every practitioner. He knew of at least two deaths that had occurred in typhoid cases.

Dr. James L. Miller of Chicago believed that Dr. Fussell's suggestion was a good one. They refused to give the injections in patients when they did not think they could stand them; they were first tested out with very small doses. He believed, however, that with proper precautions they were secure against bad results, but they should be careful in their selection of cases.

Renal Function During Acute Infections.—Dr. Channing Frothingham, Jr., of Boston presented this paper and asked what tests were available for studying the renal function at the present time. The best test was the socalled renal test and the diet test today. Another test was the estimation of the amount of fluid the kidney put out, the phenolnaphthalein test. Another test of the renal function was the estimation of the total amount of nitrogen or urea in the blood. His report was on the results of estimating the blood urea, the index of urinary excretion, and the ability of the kidney to put out phthalein. The group of cases studied consisted of young people, with no evidences of kidney disease. His results were shown by charts. The practical point given was that during the course of acute infectious diseases there was no serious injury to the kidneys, and that it was better to use a high caloric diet.

Dr. Theodore C. Janeway of Baltimore said it was interesting to note the high index of urea in febrile and other acute diseases. He recalled an instance of hyperthyroidism, which showed quite regularly an extremely marked increase in the output of urea. Another case of pneumonia showed a decrease in the high index.

A Case of Primary Thrombophlebitis of the Hepatic Vein and a Case of Primary Sarcoma of the Epicardium.—Dr. Nathan E. Brill of New York said that in the wards of Mt. Sinai Hospital they had two cases of infections which perhaps were among the rarest in human pathology. There was very little about either to be found in the literature. The first case was the first to be reported in this country.

Case I.—During the afternoon of December 4 a woman was carried into the ward moaning with pain, and she stated that she had never before been ill. She was twenty-four years of age, married four months, and pregnant two months. Her disturbance was referable to the abdomen. For four or five days before admission she suffered from pain in her epigastrium and down to the lateral aspects of the abdomen. The examinations of heart, lungs, etc., were negative. The liver was enlarged 2 cm. below the free border of the ribs. The pain was very intense and she was unable to lie down at all, and she moaned all the time. The question arose, was she suffering from some surgical condition, but as her attack was acute and a diagnosis could not then be made, she was left until the following day. The blood count was made and there were found 21,000 white cells, with 80 per cent. polymorphonuclears. On the following day the liver was found to be 4 cm. below the free border of the ribs. The fecal examination proved negative, and they were no nearer a diagnosis than before. The blood count showed 17,000 white cells and 85 per cent. polymorphonuclears. On the next day the liver was found to be larger, 7 cm. below the free border of the ribs, and for the first time the spleen was felt. On the day following the spleen was found to be three fingers below the free border of the ribs and the liver was at the crest of the ilium. There was a tremendous accumulation of fluid and the abdomen was distended to an enormous size. Dr. Brill objected to an operation, but finally consented to an exploratory one. About one liter of perfectly clear fluid was evacuated and the liver was found to be down to the iliac crest. The spleen was 4 cm. below the free border of the ribs. The uterus was evacuated at this time. She lived from the 4th to the 26th of December. The necropsy showed a liver considerably shrunken in size with a shrivelled capsule. A similar condition of the spleen was found. The abdominal viscera showed no infectious process and there was no portal vein infection. Exposing the vena cava at the entrance of the hepatic vein for a distance of 0.5 cm. was found a blood clot. This was traced along the hepatic vein and showed soft clots connected with the periphery by a little tissue. The clot extended all over the branches of the hepatic vein. There was a primary thrombus in the hepatic vein terminating at the vena cava. The diagnosis he made was wrong but near enough. In all there were but three cases reported in the literature of this nature. This woman had an absolutely negative Wassermann. This was a blood condition and with no signs of inflammatory tissue whatever. The woman died because of an utter suppression of hepatic function.

Case II.—This was a woman, 22 years of age, unmarried. She came into the hospital in June with a frank attack of pneumococcus infection, a lobar pneumonia. There was an endocarditis associated with an effusion. After a stay of a few weeks she was discharged as cured. She left in July and returned in September, and a diagnosis was then made of a pericardial effusion. On the second day after admission the pericardial sac was tapped and they obtained a small quantity of blood-stained fluid, which was sent to the laboratory. At the same time the needle was introduced in the mid-mammary line and about 2 c.c. of blood-stained fluid was obtained. A diagnosis of pericarditis with effusion was made. When Dr. Brill first examined her he found the chest flat on percussion and he felt that she had an effusion in the left pleural sac. The sounds were indefinite and he could not make out the apex beat at all. He then became skeptical about the diagnosis of pericarditis with effusion. She had developed an adherent pericardium and dilatation of the heart with a large amount of effusion in the left sac. He demonstrated this case before his students as one of polyserositis. The patient lived until the middle of January. At necropsy, when the sternum was removed, the pericardial sac was found to be 20 cm. in length, 24 cm. in width, and 14 cm. in depth. There was noted little flat creamy eminences. Upon opening the pericardium there was found a large tumor mass and a small amount of brown colored fluid. The mass enveloped the entire heart, but the entrance of the veins was not occluded at all. The tumor mass was homogeneous and was cellular in nature and was separated from the endocardium by a line of connective tissue except at the right auricle. This woman had suffered from a tumor which involved the entire epicardium. On section the tumor showed a large number of spindle and round cells; the type of these cells was embryonic. The whole thing was a delicate fine reticular structure. An important point was this: In going over the history after the autopsy the sheet on which the findings should have been recorded, there was no report whatever of the findings in the fluid. If such a report had been where it should have been he might have been able to make a diagnosis. In the body of the history sheet, however, he found a little note stating that "fluid from pericardial sac was tapped and the cells indicated malignancy," which was signed by Dr. F. S. Mandelbaum. Only eight cases of sarcoma of the epicardium had been reported in the literature. There was no metastases.

Some Points Respecting the Localization of Syphilis Upon the Aorta.—Dr. Oskar Klotz of Pittsburgh read this paper. He said the distribution of syphilis upon

the aorta was unique, being localized in certain areas more commonly than in others. When compared with other infections a similar distribution was found. In the majority of instances where infection localizes upon the tissues of the aorta, it was found to begin in the outermost layers and from here to attack the adventitia and media. The localization had been mainly ascribed to a distribution by the vasa vasorum. The reactions were found to follow the course of these vessels, making it appear that they had to do with the bringing of the infectious agents to the particular sites. On the basis of the hematogenous distribution it was not possible to account for the more frequent localization of infection upon the ascending and transverse portions of the aorta. A study of the aorta and its lymphatic distribution demonstrated a greater number of lymph channels in given regions. This was particularly true for the first portion of the aorta. The prominence of these lymphatics and evidence as serving for routes of infection was seen in several cases of pneumonia. A similar correlation of the lymphatic system to the distribution of the infectious agent was noted in syphilis. The lymphatics in the aortic wall followed the course of the vasa vasorum, thus giving rise to a perivascular infiltration which was so prominent in syphilitic aortitis. The lymphatics appeared to be more important structures for the distribution and localization of syphilis than the small nutrient vessels.

Specific Treatment of Pneumonia. — Dr. RUFUS I. COLE of New York said that he had made observations which showed that in specific exudates might be formed substances which inhibited the action of immunity principles. The treatment was tried before the observations were made. The bacteria grew in the tissues and were not free in the fluids, and they accidentally found that the fluid in the body formed substances which would overcome the bacteria if in sufficient amounts, but they must use soluble substances. They then attempted to learn if the serum used appeared in the blood and they found that if they were to render the blood immune the serum should be given early and in large amounts intravenously. There was no reason to believe that they affected the course of the disease other than by causing immunity in the patients. The results had been excellent in the Type I cases. Of great importance was the value of the serum and they learned that the blood infection was immediately overcome and body immunity occurred early. In regard to the socalled serum reactions of various kinds following the administration of immune serum, there did follow reactions of several kinds. (1) There were the intoxications due to the administration of the serum. These reactions were definite drawbacks to the treatment, and they knew of no method of preventing them. They had treated more than 200 patients with Type I and Type II. The serum should be given slowly. If the patients had any reactions, stop the treatment immediately. Some patients had a certain amount of idiosyncrasy. (2) There were the true anaphylactic reactions. These were rare. Every patient as soon as he was admitted to the hospital received the intracutaneous test to find out if he was sensitive to horse serum. This aided in sensitizing. (3) There was the serum sickness and this group of symptoms occurred in 50 per cent. of the people who received the serum. In 10 per cent. of these the symptoms were quite intense. He never had seen a case of serum sickness which ended fatally, and he thought they could entirely disregard serum sickness.

Dr. LAWRENCE LITCHFIELD of Pittsburgh said he wished to bear testimony as to the efficacy of the serum treatment of pneumonia.

Observations at the Peter Bent Brigham Hospital on Cases of Pneumonia in Relation to Types of Pneumococci and the Serum Treatment of Type I Cases.—Drs. HENRY ASBURY CHRISTIAN and H. L. ALEXANDER of Boston presented this communication, which was read by Dr. Christian. They presented studies on 187 cases of typical bronchopneumonias. A higher mortality occurred when positive cultures were found. The treatment by the serum was confined to Type I cases, 11 in all. As a rule there was a critical fall in the temperature in a few hours after the serum was given; frequently more than one dose was necessary to reduce the temperature. Sometimes there was a rise in the temperature and a chill following the first dose. All these cases were tested with the horse serum protein before the serum was given. Serum sickness occurred in most cases one week after the treatment but was never severe. There were some slight joint manifestations and a slight rise in temperature, but there were no disturbances during the course of convalescence beyond some itching and urticarial lesions. Of the treated patients, one died during the pneumonia, one died during convalescence, and two developed empyema. There was a reduction in the mortality from 42 per cent. in the untreated cases to 18 per cent. in the treated cases.

Dr. THEODORE C. JANEWAY of Baltimore presented on the blackboard some interesting tables showing the results of the serum and no serum treatment of pneumonia in the white and colored races as follows: In Type I cases treated with serum, white, 4 cases and 2 deaths; colored, 7 cases and 1 death, a total of 11 cases and 3 deaths. In Type I treated with no serum, white, no cases and no deaths; colored, 9 cases and 4 deaths, a total of 9 cases and 4 deaths. In Type II, treated with no serum, white, 3 cases and 3 deaths; colored, 15 cases and 4 deaths, a total of 18 cases and 7 deaths. In Type III, treated with no serum, white, no cases and no deaths; colored, 1 case and no death, a total of 1 case and no deaths. In Type IV, cases treated with no serum, white, 5 cases and 2 deaths; colored, 14 cases and 2 deaths, a total of 19 cases and 4 deaths. Altogether there were: whites, 12 cases with 7 deaths; colored, 46 cases with 11 deaths, a total of 58 cases and 18 deaths. This showed there was a definite lower mortality among the negroes. The reactions seemed to have a definite relation to the quantity of serum administered.

Dr. MILTON HOWARD FUSSELL of Philadelphia said that the Board of Health in Philadelphia were giving physicians the serum under the plan advocated by the Rockefeller Institute. Seven patients had been so treated in his wards with no deaths. One had a very severe reaction after being given 60 c.c. of the serum. This patient finally recovered but later developed a pleural effusion which was not purulent. The temperature did not drop to the normal as was usual in those cases not so treated.

Dr. S. J. MELTZER of New York asked Dr. Cole if the antimeningitis serum had been used and if he found any cases of empyema of established specificity. Could not the disease be overcome by the use of another serum as from Type II? Had he studied what effect the serum had upon the circulation?

Dr. RUFUS I. COLE of New York said there had not been observed any specific effect of the serum upon the circulation, but there had been some general effects. The question regarding meningitis was interesting. If the immunized serum was delayed too long, meningitis was liable to develop and death follow. In treating these patients they should bear in mind just what they wished to do; treat these patients as they treated diphtheria and they would lessen the mortality of typhoid pneumonia.

Studies on Uranium Poisoning.—Drs. HOWARD T. KARSNER and S. P. REIMANN of Boston presented this paper, which was read by Dr. Reimann, in which the following conclusions were drawn: (1) Toxic effects of certain aqueous-insoluble salts of uranium. Having in mind the possibility of the employment of uranium in the industries, feeding experiments had been carried out with uranium oxide, the salt most likely to be formed in the presence of high temperatures. Such a salt liberated as a dust could be inhaled and swallowed. A somewhat similar water-insoluble salt was sodium uranate. Uranium oxide, sodium uranate, and uranyl nitrate were fed guinea-pigs, the dose being determined by the uranium content. All were toxic and the study showed the relative degrees of toxicity. (2) Solubility of uranium oxide in artificial and human gastric juice. Having found that water-insoluble uranium oxide is toxic for animals, quantitative determinations were made of the solubility in 0.2 per cent. hydrochloric acid solution pure and with the addition of milk, whey, casein, lactose, washed butter, dextrose, peptone, etc. Similar determinations were made with human gastric juice. (3) Effects of soluble uranium salts on blood, blood plasma, and erythrocytes. These experiments

were performed *in vitro* and dealt with coagulation (?) or precipitation, methemoglobin formation, agglutination, and hemolysis. Variable doses of uranyl nitrate were employed with the blood of dog, cat, and rabbit. (4) Localization of uranium in body tissues. After injections of large doses of uranyl nitrate the organs of cats were incinerated and examined for uranium. It was found that the kidney was the only organ from which uranium could be recovered. Subsequently entire animals were perfused with Locke's solution containing uranyl nitrate. Then kidneys alone were perfused with defibrinated blood containing uranium and finally pieces of fresh tissues were soaked in uranium solutions. (5) Hydrogen-ion concentration of the blood in uranium poisoning. These experiments were performed to determine first the fact of an acidosis in uranium poisoning, and, second, the time relations of the appearance of acidosis and of the signs of nephritis.

On the Focality of Microscopic Lesions in the Brains of Certain Psychopathic Subjects, Especially in Dementia Precox.—Dr. ELMER ERNEST SOUTHARD of Boston reviewed the evidence of the focality of gross lesions (anomalies and scleroses) in dementia precox brains. The paper presented dealt chiefly, however, with microscopic findings in brains without gross lesions. The dissociation of parenchymatous (neuronic) and interstitial (neuroglia) lesions presented last year was reviewed in connection with a study of the stratigraphical analysis of the distribution of lesions found, especially gliosis (including satellitosis) and nerve cell losses. The points of the present communication related chiefly to the topography of the microscopic lesions, both neuronic and neurogliar, both in the outer layers (suprastellate) and in the inner layers (infrastellate) of the cerebral cortex. The functional correlations were briefly reviewed.

A Case of Ventricular Fibrillation in Man with Recovery.—Dr. GEORGE CANBY ROBINSON of New York presented this paper. He said that the interest in ventricular fibrillation as a disturbance of the cardiac activity of man had been centered about the role this phenomenon played in causing sudden death. It had been generally accepted that when the human ventricles passed into a state of fibrillation, death was an almost immediate and an invariable consequence. Ventricular fibrillation could be determined definitely by means of electrocardiograms. The case to be reported was one in which three attacks of syncope occurred. These lasted about four minutes each. During one of the attacks, when the patient ceased to breathe, and when no heart sounds were audible, an electrocardiogram characteristic of ventricular fibrillation was obtained. The patient lived thirty hours after this syncopal attack, during which time numerous electrocardiograms were obtained. The case was the first example of recovery from well-established ventricular fibrillation that has been observed.

The Etiology of Poliomyelitis.—Dr. EDWARD C. ROSENOW of Rochester, Minn., described the organism constantly isolated from the infection atrium and central nervous system in cases of poliomyelitis in man and from the central nervous system of monkeys with experimental poliomyelitis.

Brief Report on Microorganisms from Tonsils, Adenoids and Infected Sinuses.—Drs. C. A. LAUBACH and WILLIAM WEBBER FORD of Baltimore presented this paper. They stated that during the past year various types of microorganisms have been isolated and studied from material collected in the nose and throat clinic of Dr. Crow of the Johns Hopkins Hospital. Some 200 different specimens have been studied. The majority of the organisms found were streptococci and pneumococci. Next in order of frequency were the micrococci. Special attention has been paid to the streptococci, which are best arranged according to the classification suggested by Holman, which promises to be of great assistance from the clinical standpoint.

Atrophy of the Large Motor Cells of the Corpus Striatum in the Pre-senile Type of Paralysis Agitans; a Contribution to the Nature and Pathology of Parkinson's Disease.—Dr. J. RAMSAY HUNT of New York read this paper. He said that paralysis agitans might be subdivided into clinical types, according to the age of onset, and the character of the symptoms. There were presenile and senile types, and a rare juvenile form; also, paralysis agitans without tremor and a rare tremor type of the disease in which rigidity was absent In addition, various irregular and symptomatic forms were recognized. At a meeting of the American Neurological Association, May 6, 1916, Dr. Hunt described certain pathological changes in the juvenile type of paralysis agitans which consisted of atrophy and diminution in number of the motor cells of the corpus striatum. The suggestion was then made that paralysis agitans beginning in early life belonged to the group of motor system diseases, and was dependent upon a primary atrophy of the efferent projection system of the corpus striatum. The atrophic changes in this type of disease were limited to the motor cells of the globus pallidus and were especially marked in the large cells of similar type in the caudate nucleus and putamen. These cells of the globus pallidus type therefore represented a well defined cellular system, the globus pallidus mechanism, which Dr. Hunt regarded as the essential motor system of the corpus striatum. Juvenile paralysis agitans, acording to this conception, was a primary system disease (primary atrophy of the pallidal system) occurring in the course of the striospinal mechanism; while spastic paralysis (primary lateral sclerosis) was a system disease of the corticospinal mechanism. The present study was a preliminary report on the pathological findings in the presenile type of paralysis agitans. In two cases of this disease the large motor cells (giant cells), normally present in the caudate nucleus and the putamen, showed distinct atrophic changes. These cells were reduced in size; the processes shriveled and became tortuous; the nucleus contracted, was displaced, and stained uniformly with hematoxylon. Some of the cells showed an increase of pigment; in others the atrophy was still more marked, and the internal structure of the cell was not recognizable. The smaller ganglion cells of the caudate nucleus and putamen were not affected. The motor cells of the globus pallidus proper showed only slight alterations. Some of these cells appeared slightly reduced in size and presented a somewhat rounded or angular appearance, but these changes were not well defined and the essential lesion was an atrophy of the giant motor cells of the caudate nucleus and putamen. Dr. Hunt therefore regarded the atrophy of these large motor cells of the corpus striatum (viz. the giant cells of the caudate nucleus and putamen) as the essential lesion in paralysis agitans of the presenile type. According to this conception, the corpus striatum was a motor mechanism for the control of automatic and associated movements operating through the extra pyramidal motor tracts. The pallidal system was the motor system proper and terminated in relation to important ganglia in the hypothalamic region; viz., nucleus ruber, corpus Luysii, and substantia nigra, and through these centers exercised a controlling influence by way of the extrapyramidal system on automatic and associated movements. In presenile paralysis agitans the large motor cells of the pallidal system in the caudate nucleus and putamen were chiefly affected and these giant cells of the corpus striatum Dr. Hunt regarded as comparable to the Betz cells of the motor cortex. Paralysis agitans was characterized by three cardinal symptoms, viz., paralysis, rigidity, and tremor. An analysis of the paralytic disturbance showed that this was essentially a disturbance of automatic and associated movements, involving subordinate types of movement which were largely involuntary in character, such as walking, running, rising, sitting, grasping, etc., which, however, were under the control of the will. The peculiar rigidity of paralysis agitans was dependent upon a hypertonicity of the musculature which most authorities agreed was of central origin. This rigidity differed from the spasticity of pyramidal tract origin by the absence of reflex hyperexcitability, as manifested by exaggeration of tendon reflexes and clonus. Dr. Hunt referred to recent investigations which showed that muscle tissue was composed of two essential contractile elements: One was the anisotrophic disc system under the control of the peripheral motor neurons of the spinal cord, viz., the large multipolar cell in the anterior horn, medullated nerve fiber, and motor end plate. The other, a more plastic component, was dependent for its activity upon the sarcoplasmatic substance of muscle, which was under the control of

the sympathetic system, viz., motor sympathetic cell of the anterior horn, a sympathetic nerve fiber and end plate. The differences between the hypertonicity following lesions of the pallidal system (paralysis agitans) and the pyramidal system (spasticity) Dr. Hunt would explain by the relative degree of involvement of these two intrinsic systems of muscle tissue. He would therefore regard paralysis agitans as one of the cardinal types of motor palsy, induced by a lesion in the course of the efferent motor neurones of the corpus striatum; viz., the pallidal system. This system might be the seat of a primary atrophy or abiotrophy, as in the juvenile types of paralysis agitans (primary atrophy of the pallidal system). This system might also present evidences of senile atrophy or vascular degeneration, as in the senile and presenile type of the Parkinsonian syndrome.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

COMPEND OF MATERIA MEDICA THERAPEUTICS AND PRESCRIPTION WRITING, with especial reference to the physiological action of drugs. Based on the ninth revision of THE U. S. PHARMACOPŒIA, including also many unofficial remedies. By A. D. BUSH, B.S., M.D. Eighth edition, revised. 274 pages. Price, $1.25 net. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

THE TREE OF LIFE. By Dr. GEORGE W. CAREY. 60 pages. Price, $1.00. Published by Dr. George W. Carey, P. O. Box 293, Los Angeles, Cal.

THE NEW SYSTEM OF GYNECOLOGY. Edited by THOMAS WATTS EDEN, M.D., F.R.C.S.E., F.R.C.P., Temp. Major R.A.M.C., and CUTHBERT LOCKYER, M.D., B.S., F.R.C.S., F.R.C.P. In three volumes, with numerous illustrations in color and in black and white. Vol. I, 761 pages. Vol. II, 875 pages. Vol III, 871 pages. Published by the Macmillan Company, 66 Fifth Avenue, New York City. $36.00 for the three volumes.

THE ROENTGEN DIAGNOSIS OF DISEASES OF THE ALIMENTARY CANAL. By RUSSELL D. CARMAN, M.D. Octavo of 558 pages, with 504 original illustrations. Published by W. B. Saunders Company, Philadelphia and London. 1917. Price, $6.00 net, cloth; $7.50 net, half morocco.

A HANDBOOK OF PRACTICAL TREATMENT. By Many Writers. Edited by JOHN H. MUSSER, JR., B.S., M.D., and THOMAS C. KELLY, A.M., M.D. Vol. IV, 1,000 pages. Illustrated. Published by W. B. Saunders Company, Philadelphia and London. 1917. $7.00 net, cloth; $8.50 net, half morocco.

DESK INDEX TO MUSSER-KELLY TREATMENT TO VOLUMES I, II, III, AND IV. Published by W. B. Saunders Company, Philadelphia and London.

THE INTENSIVE TREATMENT OF SYPHILIS AND LOCOMOTOR ATAXIA BY AACHEN METHODS. By REGINALD HAYES, M.R.C.S., etc. Second Edition revised. Illustrated. 88 pages. Published by Baillère, Tindall & Cox, London, England, 1917. Price, 3/6 net.

INTERNATIONAL CLINICS. A quarterly of illustrated clinical lectures and especially prepared original articles on treatment, medicine, surgery, neurology, pediatrics, obstetrics, gynecology, orthopedics, pathology, dermatology, ophthalmology, otology, rhinology, laryngology, hygiene, and other topics of interest to students and practitioners. By leading members of the medical profession throughout the world. Edited by H. R. M. LANDIS, M.D., Philadelphia, U. S. A. Vol. II. Twenty-seventh Series, 1917. Illustrated. 313 pages. Published by J. B. Lippincott Company, Philadelphia and London. Price, $2.00.

A MONOGRAPH ON THE EPIDEMIC OF POLIOMYELITIS (INFANTILE PARALYSIS) IN NEW YORK CITY IN 1916. Based on the official reports of the bureaus of the Department of Health. Published under the direction of the Department of Health of New York City, 1917. 391 pages, illustrated.

Therapeutic Hints.

Hyperchlorhydria.—The first essential is to remove any mental or physical cause. If a definite physical cause be present, it should be treated and thus give relief of the hyperchlorhydria. If no organic condition be found, then medical treatment can be instituted. Butler begins treatment by ordering the patient from a quarter to half a dram of sodium bicarbonate, preferably in a small amount of water, an hour after each meal and occasionally during the day if the discomfort is great. Later, if necessary, the following may be given: sodium bicarbonate, sodium phosphate, sodium sulphate, āā 30 gms. (1 oz.) M. Sig. Gm. 2 to 4 (half to one dram) with ox gall pills salol coated, 0.25 gm. (4 grs.) after meals. The sodium bicarbonate may also be used with this, but in slightly smaller amount. Should the acidity continue in excessive quantity, atropine may be employed, gm. .003 to .006 (gr. 1/200 to gr. 1/100) repeated once or twice, or tinct. belladonna in gm. .02 to .05 (3 to 5 drops) doses every three or four hours, for a few times is sufficient to control the secretions and generally relieves any discomfort.

The diet must be simple. Butler has practically discarded the full protein diet and uses a carbohydrate and fruit diet. Eggs and meat, if used, must be in very limited amounts, and the patient eats only vegetables, fruit, and cereals. Occasionally the vegetables may be given in the form of a puree, but this is usually not necessary. Three feedings daily are sufficient. For breakfast these patients may be allowed an orange or a grapefruit, stewed apples, stewed prunes, etc., a cereal, preferably cream of wheat or cream of barley, but oatmeal, corn flakes, and rice are not interdicted, a soft-boiled toast or milk toast, and, if desired, a few strips of well-cooked but not crisp bacon. For lunch, rice and cream, apple sauce, a roll and tea, a glass of buttermilk with a piece of angel food or sponge cake, or a cup of bouillon an da couple of slices of bread and butter. For dinner, about 10 ounces of barley broth, vegetable soup or boillon, following this a lamb chop or scraped beef cooked rare in small amounts, the white meat of chicken or turkey, finely ground or chopped not to exceed 50 gm. may be given, but a few strips of bacon are more easily digested. Potatoes, mashed with milk or bread, are well tolerated. Spinach, peas, and asparagus tips are excellent. The various vegetables cooked in a puree offer some variety. Vichy and carbonated waters are enjoyed by the majority of these patients and can be taken three times a day in amounts not to exceed 100 to 150 c.c. (3 to 5 oz.). Kumyss can be used to replace buttermilk for variety, while olive oil one-half to one ounce, taken three times daily, aids in reducing the acidity. Colonic flushing is a strong factor in combination with th eabove treatment.—*Medical Times.*

Acute Cystitis.—A valuable prescription for relief of this condition is:

℞ Fluidextract pichi	f ℥ j	30 c.c.
Potassi nitrat	℥ j	4 gm.
Elix. simplicis	f ℥ iij	90 c.c.

M. S.—One teaspoonful every two hours, well diluted.—*Hughes' Practice of Medicine.*

THE DIAGNOSIS AND TREATMENT OF ABORTION.*

BY HIRAM N. VINEBERG, M.D., F.A.C.S.,

NEW YORK.

ASSISTING GYNECOLOGIST, MT. SINAI HOSPITAL.

THE diagnosis of abortion should, apparently, not offer any great difficulties, and still, it may, at times, tax the doctor's diagnostic skill to the utmost. The essential considerations in a given case are: (1) Was the patient actually pregnant? (2) Is the abortion spontaneous or induced? (3) Granting the presence of pregnancy, the question arises, have the products of conception been entirely expelled or removed, or are there still remnants of conception in the uterus? (4) Are we confronted with a uterine abortion or with an ectopic pregnancy, or, as occasionally happens, with the presence of both?

1. *Was the Patient Actually Pregnant?*—At the present time when women so frequently run to a doctor or midwife, or use means themselves to obtain relief, as soon as they have skipped a period for one or two days, it not infrequently happens that attempts to interrupt a supposed early pregnancy, are made when pregnancy is not existent at all. Some of the most virulent cases of septic infection that I have encountered have been in just such cases. I will cite one case out of several. It was that of a woman who, when she had passed her period for a couple of days, endeavored to bring on, supposedly, an abortion by introducing an alum stick into the uterus. The next day she had a severe chill followed by a temperature of 105°. That night she was curetted by her family physician, who thought he removed some tissue. Twenty-four hours later, when seen by me, she had had a couple more chills and a temperature of 106° and a pulse of 140. Her blood was swarming with streptococci, as the blood culture taken then showed later. It was my conviction that the only chance the patient had lay in an immediate hysterectomy, which I performed. The patient recovered. The uterus showed a total absence of any signs of having been recently pregnant, but the endometrium was in a state of gangrene deluged with streptococci. What makes these cases of attempted abortion in a non-pregnant uterus so malignant, is the circumstance that in order to infect a non-pregnant uterus, the bacteria must, of necessity, be of the most virulent variety and there is no opportunity of localization of the infection to the ovum as may occur in pregnancy. Furthermore, the attempts are likely to be repeated until free bleeding occurs, thus exposing the uterine tissues to the most severe traumatism.

Neugebauer, the great Russian satistician, in 1912 collected from the literature 15 such cases with a fatal result in 5 cases. Liebeck, a year later, collected 44 cases with death in 14 cases, a mortality of 35 per cent. In many instances, ectopic pregnancy was found in these cases of attempted abortion of a non-pregnant uterus.

Personally, I had seen so many cases of ectopic pregnancy in women who began their attempts to bring on a miscarriage, when they were one or two days overdue, that some years ago I expressed the belief that there might be some connection between these interferences and the arrest of the impregnated ovum in the tube.

2. *Is the Abortion Spontaneous or Induced?*—This may seem, at first blush, somewhat of a refinement in diagnosis, but such is not the case. Some years ago, when in charge of a large dispensary service, I made the observation that a spontaneous abortion or miscarriage, whichever term you wish to employ, is with definite exceptions, never attended with fever. The exception is when the pregnant uterus lies in retroversion or retroflexion and drainage is interfered with. So firmly convinced am I of the reliability of this observation, that when an aborting patient with fever presents herself to me, I straightway accuse her of having had some interference, either by herself or others. No matter how strongly she may deny this, at first, it has been my invariable experience that sooner or later she will admit it. I recall one instance which, at first, seemed to shatter the infallibility of the observation. It was the case of a young woman, pregnant about two months, who was bleeding rather profusely and who had had a chill four days before, and since then a temperature ranging from 101° to 104°. The patient denied stoutly any interference and the circumstantial evidence was strongly in support of her assertion. She had lost the only child she had had and was keenly eager to have another. The case puzzled me considerably. The patient was admitted into Mt. Sinai Hospital, where I shelled out, from the open cervix, the products of two months' pregnancy. The temperature, nevertheless, persisted. I made a tentative diagnosis of typhoid fever. She was seen by one of the internists, who stated he could see no evidence of it, and, a Widal taken proved to be negative. I adhered to my diagnosis, feeling firmly convinced that the spontaneous miscarriage could not be the cause of her continued fever. Later, the Widal was positive, but

*Read before the East New York Medical Society May 17, 1917.

by this time the clinical evidences were so unmistakable as to leave no room for doubt. The disease ran a most violent and protracted course, but finally ended in recovery.

3. *Is a Given Case One of Complete or Incomplete Abortion?* in other words, is the uterus completely empty, or are there still some remnants of the products of conception within the uterine cavity? It may be readily assumed that the presence or absence of bleeding would, of itself, be sufficient evidence whether the abortion was complete or not. As we all know, this is not always the case. The bleeding may have ceased and still the uterus may contain considerable products of conception. Here a bimanual examination will be of great aid in reaching a conclusion, particularly, if the pregnancy was advanced beyond 6 or 7 weeks. When this is the case, there would be appreciable enlargement of the uterus. In very early pregnancies, we may guide ourselves, in the majority of cases, by the absence or presence of bleeding. If there be no bleeding nor fever we are safe in assuming that the abortion is complete. This point will be discussed again, when we come to speak of treatment.

There is a condition to which I would wish to draw your attention, which frequently is rather puzzling. A woman may have had amenorrhea for 6 or 8 weeks and then begin to bleed in various amounts, at times very profusely, at other times rather scantily. When we come to make a bimanual examination, we are surprised to find a uterus reaching to the umbilicus or beyond. We may be led to believe the woman has made an error in the calculation of the date of the pregnancy, or that she has a fibroid growth complicating her pregnancy. When such a discrepancy occurs between the clinical history and the local findings, you must always bear in mind the probability of a hydatid mole. The suspicion will be confirmed, if the much enlarged uterus be unusually soft and doughy. The age of the patient may be of some aid in diagnosis. Molar pregnancy is more frequently met with in multiparæ, who are approaching the menopause. Still, I have met with two cases in very young women, 20 and 21 years of age respectively, and in each instance it was the first pregnancy. In one of the cases a severe attack of eclampsia was present.

Occasionally we meet with a patient in whom the exact opposite condition to the foregoing is present; the woman dates back her pregnancy to 4, 5, or 6 months and on bimanual examination we find a uterus corresponding in size to the gravid organ at 8 or 10 weeks. Here we have what is termed a "missed abortion." If we interrogate these patients very carefully we will learn that, at some time or other, in the early period of pregnancy, they saw a stain or two, to which they attributed no significance. That usually marks the death of the ovum, but it is retained in the uterus, forming almost a solid mass, known as a "fleshy mole," or a sac with very thick walls, inclosing more or less fluid and a small shriveled fetus. This condition seems rarely to be recognized by the practitioner. The patients usually consults him because she finds her abdomen is not increasing in size as it should. At the first examination he usually tells her everything is all right. At a second examination, a month or two later, he may tell her she has not been pregnant at all. I see a case of this kind in my office every month or two and cannot recall an instance in which the correct diagnosis had been made by the medical attendant.

4. *The Differential Diagnosis Between an Early Abortion and Ectopic Pregnancy.*—In former years, the error of confusing an ectopic pregnancy for an early miscarriage was very common, and one frequently met with cases of ectopic pregnancy that had been subjected to one or more curettages, and the surprise was expressed that the bleeding still persisted. Now, I should say the tendency is rather in the opposite direction. But, on the whole, it is a safer tendency than the previous one. It is still a good maxim to look upon every case of supposed spontaneous early miscarriage with suspicion. The suspicion should be strengthened when the uterus is found but slightly larger than the normal, and when the cervix is found closed. Many writers make the differential diagnosis appear exceedingly easy and so it is, in some cases, as, for instance, when there are the classical symptoms of severe cramp-like pains, limited to one quadrant, fainting spells, and a distinct and appreciable enlargement of the affected tube. But we know that cases presenting this triad of symptoms are rather the exception than the rule. What renders the diagnosis so difficult at times is the circumstance that nowadays women so frequently seek relief when they are a few days over due, as has already been stated and as we all only too well know. In a given case, therefore, we may be confronted with the problem whether we are dealing with a case of attempted abortion at an early period of pregnancy, with thickening of one of the tubes as a result of infection, or with an ectopic pregnancy in which an attempt at an abortion has been made. In both instances we have slight enlargement of the uterus associated with thickening of one or the other of the tubes, and I frankly confess that I have not infrequently met with such cases in which I found it impossible to make a definite diagnosis. A differential blood count is of no aid to us in these cases, for the white blood count is considerably increased in ectopic pregnancy as it is in an infected salpingitis. When such a problem presents itself to me, in order to establish the diagnosis, I am in the habit of carefully curetting the uterus and, on finding it empty, I make an incision through the posterior vaginal vault, and if free blood escapes from the peritoneal cavity, I open the abdomen from above and excise the ectopic tube. It is better, occasionally, to make an unnecessary exploration of this kind, than to allow one case of ectopic pregnancy to escape our observation. Of course, when the symptoms are not urgent, we can afford to wait a week or two, to observe whether the uterus increases in size.

Every now and then we meet with uterine abortion associated with ectopic pregnancy. I can recall three such cases in my experience. Every one of us is likely to slip up in the presence of such a combination. In one instance I made the diagnosis of ectopic pregnancy, but the family physician felt certain of his diagnosis of uterine abortion, and insisted that I curette the patient in her home, before he would consent to her being sent to the hospital. On curetting her, I removed undoubted products of pregnancy. The family physician was

crowing over the correctness of his diagnosis, when the patient suddenly went into collapse and her entire body became blanched, as white as a sheet. I at once opened her abdomen with scissors (the only cutting instrument I had with me), and found the entire abdomen distended with fluid blood, due to rupture of an ectopic tube. By ligating the tube and removing it, filling the abdomen with saline solution and performing intravenous saline transfusion, I was enabled to save the patient.

We are now prepared to take up the treatment of abortion. First, that of spontaneous abortion without fever. If the bleeding is not excessive we can afford to wait to see what nature will do. In many instances the uterus will expell the ovum and its membranes entire, or, at most, they will remain in the dilated cervix, whence they can be readily removed with the fingers. In other cases, if the bleeding is profuse, we can either tampon the cervix with gauze and wait for the natural forces to expel the uterine contents, or dilate the cervix with a suitable dilator and remove the contents with the fingers, placental forceps, or curette. To my mind, it makes no difference which of these means is employed, so long as all the products are removed and no traumatism inflicted. Personally, I am in the habit of using the placental forceps first and then gently curetting the interior of the uterus, to make certain that all the tissues are removed.

In early abortions, say that of six or eight weeks, when the bleeding persists after the ovum and its envelopes have been apparently expelled, I find the sharp curette of great value to remove the small remnant within the uterus. It has often been a surprise to me to note how small a remnant may be the cause of profuse and protracted bleeding.

When we are dealing with infected abortions, as indicated by fever, our course must be carefully considered. First and foremost we must determine whether the prior interference (for, as I have already stated, the presence of fever, with a single exception, is an indication that a criminal abortion, or an attempt at it, has been made), has resulted in removing all the uterine contents or whether the uterus still contains the products of conception. However we may differ in treatment of the latter condition, we are all in accord as to the course to follow in the first contingency. Nothing but harm can result from subjecting an empty septic uterus to active instrumentation. I have not the least doubt that the bad reputation the sharp curette has acquired in many quarters in due in great part to its frequent employment in such conditions. We have already seen how difficult the determination, whether the uterus is empty or not, may be in a given case. Therefore, when we are in doubt we should refrain from curetting the uterus. From my own observations I should conclude that just the opposite most frequently obtains. Just because there is fever, a curettage is done, and if the fever persists a second curettage is resorted to, in the conviction that the first curettage could not have been thorough enough. The worst cases of post-abortive septic infection that we encounter in the hospital have been cases in which this line of procedure had been carried out. We have already drawn attention to the cases of virulent infection following attempts at abortion of a non-pregnant uterus.

These cases of post-abortive septic infection should, therefore, be treated on the general principles of septic infection, rest in bed, plenty of fresh air, proper nourishment, and proper action of all the emunctories.

When we come to the treatment of infected cases with the products of gestation partly or wholly within the uterus, we reach debatable ground. The discussion has arisen only since 1911, when Winter of Koenigsberg published his rather startling paper, advocating a "let-alone" policy, regarding this class of cases. To be more definite, Winter became dissatisfied with the very high mortality (13 per cent.) and large percentage of morbidity the statistics of his Klinik showed with active treatment. Consequently he instituted a different line of procedure. Every case had the uterine discharge subjected to a bacteriological examination, and if it contained virulent bacteria, such as the hemolytic streptococci, the uterus was left alone until the fever subsided and then the contents were removed.

Winter's article created a great stir in Germany and formed the basis of several publications and discussions, only a very small minority were in agreement with Winter's contention, while the vast majority were in strong opposition to it. In this country, and particularly in this vicinity, there appears to be a tendency to accept the teachings enunciated by Winter. Theoretically they seem very plausible, for example, the danger of exciting a general infection through the manipulation of the interior of the uterus and setting free the bacteria to enter into the general circulation. But practical experience, I think; has taught us the fallacy of this teaching. At least, that is the lesson I have learned from my own experience. In order to test the correctness of my conception, I had the Records of the Gynecological Service of Mt. Sinai Hospital, for the past five years, gone over very carefully. They revealed that during this period there were 287 cases of either inevitable or incomplete abortion; of these there were 60 cases which had a temperature ranging from 101° to 106°. Many of which had admitted to instrumental interference, either by themselves, midwives, or doctors, and we are safe in the assumption that all had been tampered with. All of the 60 cases had been curetted or the uterine contents removed, by other means, as promptly as it was feasible, after their admission into the hospital.

In the entire series there were but two deaths. One died 9 hours after the curettage with symptoms of pulmonary embolism. The other died of septic pneumonia on the ninth day following a curettage, performed by the then incumbent house surgeon, who perforated the uterus. The temperature ranged from 101° to 103° during the next few days, and then developed signs of pelvic peritonitis and septic pneumonia. I have not been able to collect the cases in my private practice, they were all emergency cases, calling for immediate treatment and no notes were taken of them. But I am convinced the number was quite considerable, accumulating, as they have been during several years. I can recall no mortality amongst them, the only deaths I can recall occurred in those cases seen in a moribund condition, in which intervention of any kind was out of the question.

I can see no valid reason, therefore, to change the method I have been following for very many years. There are a few lessons I learned early in my career, one of which is never to insert gauze into the uterus for the purpose of drainage. Formerly I was in the habit of irrigating the uterus, after the curettage, with 50 per cent. alcohol. Latterly I have been using a solution of tincture of iodine of the color of red wine.

There are a few points upon which I wish to lay especial emphasis. No curettage should be done without shaving off the hairs of the vulva and scrubbing the vulva afterward with soap and water gently but effectively. This procedure, one would think, is universally followed and still I cannot recall a case admitted to my service at Mt. Sinai Hospital, when a curettage had previously been done at home, in which this simple but essential procedure, had been carried out.

I am aware that there are a great many prominent and distinguished gynecologists, who object very vigorously to the use of the sharp curette. I will not deny that it is an instrument capable of great harm when not carefully employed, but it has been my experience that more serious injuries have been inflicted with the uterine steel dilator and placental forceps than with the sharp curette. It is not so much a question of the instrument as it is of the man who handles it. I have no quarrel with the man who feels he can remove all the uterine contents more safely with the fingers than with the placental forceps. But I do not expect him to quarrel with me because I find I can do it just as safely, but more thoroughly, with the sharp curette.

When I am confronted with a case of inevitable abortion, at a period of pregnancy longer than 10 weeks, I have, for years, resorted to anterior colpotomy or vaginal cesarean section. Before I adopted this method, I used to dread the task of having to empty a pregnant uterus at the third, fourth, or fifth month. It was always a tedious undertaking, attended with a great deal of bleeding, with considerable uncertainty as to whether everything had been removed, and with the constant fear that the uterus might be perforated. It was usual, also, that in removing the fetus piecemeal, the head would be severed from the trunk and the spherical object rolling about the uterus, was extremely difficult of removal, trying to both the temper and the patience of the operator. With anterior colpotomy all this is done away with. The procedure now becomes a truly surgical one, unattended with excessive bleeding and with the uncertainty of groping about in the dark. By making a longitudinal incision and exercising due care in coaptating the edges of the wound, the anatomy of the parts are left practically in a normal condition. The risk of entering the bladder can easily be avoided by drawing down the cut edges of the cervix by successive applications of the bullet forceps, and by pushing up the bladder with the gauze-covered finger.

In hydatid mole it is the procedure *par exeellence*, at all periods of pregnancy. It enables us to make use of the fingers or the hand, to scoop out the hydatidiform masses, which are not easily removed in any other way. It enables us to determine, with a certainty, that all the contents are removed and that none of the degenerated villi are left attached to the uterine wall, to form a nidus for a probable development of a chorioepithelioma, and what is not less important, it enables us, also, to palpate the entire uterine wall, to determine whether a chorioepithelioma has not already developed.

In one of my cases of hydatid mole, this maneuver led to the detection of a hard excavated nodule in the inner uterine wall, which I had no hesitation in diagnosticating as a chorioepithelioma. I then and there removed the uterus, the miscroscopic examination confirmed the diagnosis, and it is not a stretch of the fancy to assume that this early detection of the malignant growth was the means of saving the patient's life.

In conclusion, let me say that the diagnosis of complete or incomplete abortion is often surrounded with great difficulties, demanding more thought and consideration than is frequently given to it. I find that a common error is to assume too much from the patient's history and not to pay sufficient attention to a careful local examination.

Then as to the matter of instrumental interference, an entire evening might be consumed in relating the instances of fatal septic infections and injuries to the pelvic viscera of a fatal nature, that have been caused by the abuse of the curette. Every practitioner feels himself competent to perform so simple an operation as a curettage and so he should be. But, either through ignorance or carelessness, I believe the curette has done more harm than any other single instrument in the surgical armamentarium.

I have already indicated my own views as to the proper use of the curette, and I believe that every practitioner could readily learn to so use it. But my daily experience in private and public practice demonstrates to me that men commonly use it, ignoring the very rudiments of aseptic surgery. The patient frequently is merely placed across the bed and is subjected to a curettage, even without ether and practically never with having the vulva properly prepared. Is it then a matter of surprise that the curette has been condemned so strongly in many quarters? If men were in the habit of opening the abdomen with the same lack of preparation and the same lack of asepsis, the scalpel would properly receive equally strong condemnation. And yet, in my opinion, the same care in preparation and in asepsis are required in a curettage, as in a laparotomy. That, I may truly assert, has been the guiding principles in my own work, and it is my firm conviction that the absence of untoward results has been in a great measure due to the adherence to these principles.

751 Madison Avenue.

The Christian Name of the Late Professor Doyen.—Few medical men knew the full name of the late celebrated French surgeon Doyen. Like many of his countrymen with large practices, he preferred to be known solely by his surname. His full name is said to have been Louis Eugene Doyen.—*Il Policlinico.*

Hysterical Progressive Myoclonus.—Trocello reports a case of hysterical hyperkinesis which seems to belong to the myocloni. Chorea and generalized tic could be excluded. A progressive course has not often been noted in a hysterical.—*Il Policlinico.*

INFANT FEEDING.

By MARK S. REUBEN, M.D.,

NEW YORK.

ASSISTANT IN DISEASES OF CHILDREN, COLUMBIA UNIVERSITY, IN CHARGE OF THE INFANT FEEDING STATION.

In the last six years that I have had charge of the Infant Feeding Station connected with the College of Physicians and Surgeons, the question which I have most frequently been asked by the many physicians who have visited our station has been: "Doctor, how can you tell what formulas to put these babies on?" To answer this very pertinent question properly one must understand the fundamental principles which underlie the art and the science of infant feeding.

Infant feeding is simple and can be made successful in the great majority of cases if one keeps in mind the underlying fundamental principles. These principles are few, clear cut, definite, of almost mathematical exactness; disobedience of these rules leads invariably to ultimate failure; one can attain a successful result in the great majority of feeding cases by simply adhering to the fundamentals of this science. Attention to the smallest details is the key to success.

It is only in about 10 per cent. of difficult feeding cases that special knowledge not within the scope of the general practitioner, is required. The idea is prevalent that infant feeding is a very difficult subject to grasp and this explains why so many physicians dread to take up the study of this relatively simple science and resort to proprietary foods; a procedure which is surely an admission of ignorance. That infant feeding can be made both simple and successful in the great majority of cases we can attest to from an experience of over 5,000 cases; in not a single case did we resort to any of the proprietary foods; we have yet to meet the infant that could not be made to thrive on fresh cows' milk properly modified, that would thrive on a proprietary food; it is only in cases where fresh milk can not be obtained that proprietary foods are permissible for short periods. The mortality at our station has been one of the lowest in the city, in spite of the fact that the general infant mortality in the district from which our material was entirely derived is the highest in the city; in not a single case did scurvy or rickets develop in a white baby.

Before we can prescribe an intelligent formula we must have a complete history of the mother and the infant from the day of conception to the present day, and we must make a complete physical examination of the infant to see that the case is a feeding case only, and that the malnutrition is not due to an underlying constitutional disease, which must be treated, before we can expect any success from the feeding formula.

A careful history in the majority of cases reveals the errors which have been committed in the past and points out the direction in which the formula must be corrected. We must know whether the mother suffers from a disease which is apt to be transmitted to the infant (tuberculosis, lues, etc.); we must also learn the state of health and nutrition of the mother during conception, the nature of the labor, and whether the infant sustained any injury during childbirth or not. The birth weight must always be noted; if not definitely known, one should ascertain the knowledge of whether the infant was a large or small baby at birth; this information is important in judging future progress. We must also know all the ailments which the infant has gone through since birth; these data are important because infants showing symptoms of exudative diathesis have a diminished tolerance for fat and to see whether the malnutrition is not due to improper feeding.

The most important part of the history is that which pertains to the feeding from birth up to date. How long was the infant breast fed? How frequently and for how many minutes was it nursed at each nursing? Was the infant nursed from one or both breasts at each feeding? How many times was the infant nursed during the night? Was the infant gaining in weight while on the breast? Was vomiting present? How soon after the nursing? After every nursing? Was it forcible or projectile (pyloric stenosis)? What was the nature of the vomitus—was it plain milk (due to overfeeding), curdled milk (due to too high fat), was it sour water (too high sugar)? How were the bowels—normal, loose, or constipated? Did the baby cry much after nursing (scanty milk), or did it fall asleep immediately after nursing (milk sufficient)? Did the infant cry much before nursing time was due and did it hang on the breast for a half hour or longer at a nursing (scanty milk)? How many of the children were successfully breast fed by the mother? The nursing history of the mother is of help in determining whether it is advisable to make further attempts to nurse the infant; however, very often with proper regime a mother may be able to nurse an infant when she could not nurse any of her previous infants. A poor nursing history is no excuse for not trying breast feeding in any case. Why was the infant weaned? What was the best weight when the baby was on the breast? From the answers obtained we can determine whether the infant was weaned for adequate reasons or not; very often infants are weaned without sufficient reasons; however, the pendulum has swung the other way, and now many infants are kept on the breast for weeks when everything points to ultimate failure. We should encourage maternal nursing in every case in which the milk agrees with the infant; when the quantity of breast milk is insufficient we should not wean entirely, but should partly nurse and partly feed the infant artificially.

After we have found out how the infant behaved on the breast and why it was weaned, we must inquire about all the artificial foods which the infant has received and how long he was kept on each, and how he reacted to each (what symptoms he presented—how much did he gain), how each food was prepared, how much was given at a feeding and the length of the intervals; we must know the total amount of food given and the number of feedings (also night feedings). To perceive the full significance of the value of each food, we must reduce each food to calories and to percentages. Attention to smallest details is important, such as method of preparation of the food, method of obtaining the desired number of ounces of milk, method of measuring the milk, the sugar and the water, how the bottles are given and the temperature of them,

the kind of bottle and nipples that are used, and the size of the hole in the nipple (are pacifiers used?) and finally we must inquire into the general cleanliness in the preparation of the food (are bottles and nipples boiled) and the general hygiene of the infant—sufficient care and attention, proper airing and bathing, proper clothing.

A consideration of the symptoms which the infant may present is important. 1. Appetite. If the food is insufficient the infant will cry immediately after the bottle has been given and long before the next feeding is due; the bowels are apt to be constipated and he is apt to vomit (due to the restlessness, crying and agitation) (constipation is due to insufficient residue). When an infant is overfed his appetite is poor; he also cries a good deal (overdistention, colic); he may vomit immediately after feeding (too great quantity) or some time after feeding (overfeeding with fat); the bowels, in cases where the vomiting is excessive are constipated; otherwise they are loose (due to excess of fatty acids—moderate amounts of fat cause constipation; excessive amounts of fats or carbohydrates cause diarrhea). Overfed babies are apt to have skin rashes (urticaria, eczema, intertrigo, furunculosis) and usually have a diminished resistance to infection, especially infants overfed with carbohydrates.

2. Vomiting. This may be due to overfeeding (the quantity at a feeding too great, the per cent. of fat, sugar or protein may be too high), to underfeeding, too short intervals, to mechanical causes (too much handling after feeding, abdominal pressure, overdistention with gas, too rapid or too slow feeding, the food too cold or too hot), to pyloric stenosis. It is also important to know how soon after the feeding the vomiting takes place, how often it recurs, and what the nature of the vomitus is? Vomiting due to overfeeding usually takes place immediately after feeding; it is a simple regurgitation, neither forcible nor projectile. In fat indigestion the vomiting takes place some time after feeding and the vomitus consists of creamy rancid-smelling curdled wilk; in sugar indigestion the vomiting usually takes place soon after feeding and the vomitus consists of sour-smelling watery fluid. The vomiting in protein indigestion usually takes place some time after feeding and the vomitus is cheesy and consists of large tough curds. When vomiting is due to overdistention with gas it is explosive in character and usually takes place after a period of crying and distress; to obviate vomiting from this cause the infant should be held in the upright position immediately after the feeding, and should be gently patted on the back or the abdomen to facilitate the expulsion of the gas; the nature of the vomitus depends on the length of time after the bottle has been taken. In pyloric stenosis the vomiting is projectile; the vomitus usually contains rancid-smelling creamy material and pathological elements; the quantity vomited is often in excess of the amount taken at the last feeding.

3. The Stools. It is important to know how many stools the infant has in the 24 hours; is the infant constipated or has it loose stools? What is the color of the stool? Are there any foreign elements such as curds, pus, mucus, blood or starch granules present? From the nature of the vomitus and the character of stool definite conclusions can in many cases be drawn as to the cause of indigestion (whether it is due to fat, sugar or protein). Is flatulence or colic present? These are usually due to overabundance of carbohydrates but may also be due to indigestion of fat or protein or to the swallowing of great quantities of air.

Constipation depends more on the fats and the salts than on the proteins; high fat feeding causes soap stools and consequent constipation; loose stools are caused by high content of sugar and salts in the food; a high protein and a high fat content favor an alkaline intestinal secretion and are conducive to the formation of solidly formed stools.

The stools in sugar indigestion are loose, green, and scald the buttocks; the odor is that of acetic or lactic acid; the abdomen is usually distended with gas; in severe cases fever, glycosuria and signs of intoxication are present; both sugar and starch may be present in the stool.

In fat indigestion the stools are gray or white and are greasy or shiny; the stools smell strongly of butyric acid; the stools usually contain soft curds. When the soaps predominate they are dry and hard and are clay colored or oily; the reaction of these stools is acid and the odor is rancid. The gray stool is usually due to an excess of neutral fat; the white or soap stool is due to an excess of fat in the form of soaps. There are three requisites for the formation of soap stools: (1) A moderate amount of fat; (2) considerable amounts of casein and calcium salts; (3) an absence of large amounts of carbohydrate in the food.

In protein indigestion the stools are loose, brownish, alkaline and of putrefactive or fecal odor; very often they contain considerable amounts of mucus and hard or protein curds.

In very loose stools there is a great loss of fat; the loss of fat runs parallel with that of water; the greater the water loss the greater the loss of fat. In very loose stools there are no soaps found at all (about 8 per cent); most of the fat is in the form of neutral fat (65 per cent.) and fatty acids (27 per cent.). The amount of protein lost is about twice as great as in normal stools but the relation of nitrogen to the total residue is normal; most of the nitrogen excreted is derived from the intestinal secretions and not from the food. The actual amount of calcium in the loose stool is nearly the same as in normal stool; but the quantity of Na and K in loose stools is very much increased. The residue (cellulose of bacterial origin) is very much increased in very loose stools.

The reaction of the artificially fed infants stool is alkaline; that of the breast fed is acid; the reaction depends on whether the nitrogen free elements (carbohydrates) or the fat and protein predominate in the mixture; if the former is found in excess the reaction is acid; if the latter it is alkaline. Thus an acid stool which scalds the buttocks may be changed into an alkaline stool by increasing the proteins and fats and by diminishing the carbohydrates; an alkaline stool may be changed into an acid stool by increasing the carbohydrates. Stools which scald the buttocks are usually acid.

Curds make their appearance in the stool both in fat and protein indigestion. The protein or casein curds are bigger, bean-shaped, hard, tough,

and are white or yellow in color; the fat curds are smaller, softer, more easily broken down, and are of yellow green color. The total loss of food in fuel value in the curds is in the great majority of cases very slight. The hard curds are derived from the casein and usually disappear when the milk is boiled; the soft curds are derived from the fat of the food.

4. The temperature should always be taken; healthy infants have a monothermia which becomes disturbed in nutritional disturbances; in dyspepsia and intoxication it is elevated, and in marasmus it is subnormal.

5. Sleep. How many hours does the infant sleep? How soon after the feeding does the infant fall asleep? Is sleep peaceful or restless and disturbed.

6. Crying. Is it excessive? Does the infant cry before feeding time or immediately after feeding?

7. Infections and Dermatitis. Healthy infants are characterized by a high degree of immunity to infections and freedom from skin affections. Has the infant had any infections such as influenza, repeated bronchitis, pyelitis, etc.? Has the infant had eczema, urticaria, intertrigo, furunculosis?

8. General Physical Development. Is the infant fat and flabby? What is the tone of the musculature? What is the hemoglobin? What is the size and shape of the head, chest and abdomen? How are the epiphyses and the spine? What is the condition of the gums? Does the infant support its head? Sit up? How many teeth? The whole physical development should be compared with that of a healthy infant of the same age.

After a thorough physical examination of the infant has been made and a complete history has been taken we are in a position to prescribe an intelligent formula. Close analysis of the answers received to our questions will enable us to ascribe the malnutrition of the infant to one or more of the following causes:

A. Formula, Proper.—(1) The presence of some constitutional disease, such as lues, tuberculosis, pyloric stenosis, cleft palate, congenital heart, exudative or neuropathic diathesis, etc. (2) Too much or too little food (total in the 24 hours). (3) Too much or too little at a feeding. (4) Fed too frequently or too infrequently (too many or too few feedings in 24 hours). (5) Food improperly prepared. (6) Food improperly administered (too hot or cold; given too fast or too slow). (7) Contaminated or poor milk. (8) Faulty hygiene; lack of fresh air, overheating, lack of proper bathing and clothing, lack of mothering, institutional life.

B. Formula, Improper.—(1) Fats too high or too low. (2) Sugars too high or too low. (3) Proteins too high or too low. (4) Salts too high or too low. (5) Water too much or too little. (6) Improper relations of the elements to one another.

In the presence of any constitutional disease a perfect milk formula will not cause proper gain in weight until the underlying constitutional disease had been properly treated. Under these circumstances it would be useless to change the formula every few days, for the infant will not thrive in spite of all changes of food; very often the disease is aggravated by improper feeding; it is therefore doubly important to be sure that the infant has a proper formula, and when convinced of its propriety not to change it too frequently until the underlying disease shows signs of improvement as a result of treatment.

One reason why infants do not gain in weight is because they receive too much or too little food; the percentages may be correct, but the total quantity of food may be too little or too great. Observations on breast fed infants have shown that a healthy breast fed infant requires about 100 calories to the kilo in the first three months, 90 in the second, 80 in the third, and 70 from the ninth to twelfth month; artificially fed infants require from 10 to 20 calories to the kilo more than breast fed infants. The smaller the infant, and the less the infant weighs for its age, the greater is the caloric requirement; thus puny and atropic infants require about 130 to 160 calories to the kilo; all things being equal a quiet infant requires less calories than an active one; the larger the infant is for its age the less is the caloric requirement.

One must always remember that it is not the number of calories introduced, but the number of calories properly oxidized that are of use to the infant; therefore the mere estimation of the number of calories in the food of an infant with disturbed digestion can serve no useful purpose. Foods yielding the same number of calories will not produce the same gain in weight; of two foods, one rich in fat and low in carbohydrates and salts, and the other low in fat and rich in carbohydrates, salts and protein, more must be given of the former than of the latter to procure the same gain in weight; from these facts we see that from the mere estimation of the calories in the food we cannot determine whether the infant receives too much or too little food; no two infants of the same age require the same number of calories to thrive on; the determining factors are the weight for its age, the size, and the degree of activity, the previous state of nutrition, and other factors.

Certain facts we have learned empirically; these are first, that few infants will gain in weight on less than 35 calories to the pound; second, that very few puny or atrophic infants require more than 75 calories to the pound; it is evident that what is too much for one infant may be too little for another and vice versa; the only proper way of determining the number of calories necessary for any particular infant is to begin with 35 calories to the pound and gradually to increase the number of calories in the food, until the infant begins to gain sufficiently. The only accurate way we have of determining whether the amount of food is too much or too little for any particular infant is therefore clinically; an infant who receives too much food does not finish the bottle, and is not hungry at the next feeding time; usually regurgitates and the bowels are loose. An infant that is underfed cries immediately after feeding, and long before the next feeding time is due; the bowels are constipated and there is no gain in weight.

The quantity to be given at a feeding depends on the age, the weight and the state of nutrition of the infant, also on the number of feedings and the length of the intervals. A healthy infant of normal weight can take: At the end of one month, 3 ounces at a feeding; 2 months, 3½ ounces; 3

months, 4 ounces; 4 months, 4½ ounces; 5 months, 5 ounces; 6 months, 6 ounces; 7 months, 7 ounces; 8 months, 7½ ounces; 9 months, 8 ounces. The amount of 8 ounces at a feeding should not be exceeded under one year of age. The quantity at a feeding to be given to a puny or an atrophic infant depends more on its age than on its weight; both factors must be considered; a good rule to follow in these cases is to give more than the weight and less than the age would indicate; the more an infant is underweight for its age the greater is the water need; thus a baby weighing 7 pounds at 2 months would get 3 ounces at a feeding; 7 pounds at 3 months, 3½ ounces; 7 to 8 pounds at 4 months, 4 ounces; 9 pounds at 5 months, 4½ ounces; 10 to 12 pounds at 6 months, 5 ounces. The longer the intervals the more can be given at a feeding and vice versa; infants can often be given more than the anatomical capacity of their stomachs would indicate, because a good portion of the feeding goes directly into the duodenum, immediately after its entrance into the stomach (this explains why puny infants can often take large quantities of fluid without vomiting). At times when too little is given at a feeding the babies cry and fret so much that they vomit the little they get; in these cases to allay the vomiting we must increase the quantity given at a feeding.

No infant should receive more than 7 feedings in the 24 hours, and should never be fed more frequently than every three hours; when they receive 2 to 3 per cent. fat in their milk mixture the intervals should be 3½ hours and the number of feedings 6; and when they receive 3 to 4 per cent. fat the intervals should be 4 hours and the number of feedings 4 to 5 in the 24 hours. The fat in the food is the last element of milk to leave the stomach; the higher the percentage of fat in the mixture the longer the intervals must be, otherwise there will be residual food in the stomach at the next feeding. Part of undigested milk leaves the stomach as soon as it enters it; then the whey (containing the salts and sugar) passes into the duodenum, then the partly digested protein and finally the fats. It is evident why infants with sugar indigestion usually vomit early, and those with fat indigestion usually some time after feeding (in the latter group of cases the intervals should be made longer).

Very often the infant does not thrive because the milk mixture is not prepared properly; the formula may be correct, but the preparation of it may be faulty; thus very often when skim milk is ordered the mothers after skimming off the fat usually pour it back into the mixture; and very often when top milk is ordered from two different bottles they use only one. It is important therefore to question the mother as to how she obtains the milk ordered and how she prepares it; also how she measures the sugar, the water, and other elements that may be ordered; all directions for feeding and formula should be written with the care and accuracy of a drug prescription.

Not infrequently an infant will not gain in weight and have symptoms because the food is given too slowly or too fast; an infant should not take less than 10, nor more than 15 minutes, in consuming a feed of 6 ounces; when the bottle is given too slowly the infant often swallows considerable amounts of air, and this causes distention, colic, and vomiting; when food is given too fast it is also apt to be vomited; the infant's stomach is very sensitive to all slight irritations from within and without; therefore all necessary handling and bouncing of infants immediately after feeding should be avoided. If the food is not of the right temperature (about 100° F., tested by pouring on wrist) it will often be rejected by the infant and if taken will cause vomiting and loose stools. Pacifiers should not be allowed; they are unsanitary, apt to cause infection and very often lead to swallowing of air with resultant colic and vomiting.

The milk used for infants should be the best obtainable; only grade A bottled milk should be used; no loose store milk should ever be used on account of the danger of bacterial contamination; when absolutely sure that the milk is clean it can be given raw; in summer time it is best to pasteurize or bring the milk to a boil; all infants fed with pasteurized or boiled milk should receive fruit juices early and in sufficient quantities to prevent the development of scurvy.

Not infrequently one finds infants who have not gained one ounce in weight for from 6 to 12 weeks, during which time they have had hardly any symptoms; there is no vomiting and the bowels are regular; the number of calories in the food supplied seems sufficient, and the technique is faultless; almost invariably these infants begin to gain in weight when the previous whole-milk formula is changed for one of skim milk with a high percentage of carbohydrates, although the total number of calories in both formulas remain the same; thus, there are infants who thrive best when the fats are low and the proteins and carbohydrates high, and *vice versa;* however, the great majority of infants do best on formulas in which the fats and the proteins are found in equal proportions; this explains what is meant by the proper relation of the elements to one another; in every case the relation of the elements must be such as to be within the power of digestion of the particular infant.

The food requirement during growth is peculiar in that the intake of certain groups of nutrients (proteins, salts) must exceed the wear and tear so that some excess will be available for new cells and the elaboration of tissues that develop in the period of growth. The diet of the infant is comparatively low in protein; for growth 7 per cent. of the total intake must be protein and for maintenance only 5 per cent. of the total energy intake (*i. e.* ¾ to 1½ ounces of milk per pound weight). Protein is an essential constituent of an infant's food; the protein of milk is composed of casein and lactalbumin; proteins are composed of amino acids (19 to 21). It has been found that growth depends on the presence of certain of these amino acids in the infant's food; normal nutrition is not possible unless lysin, tryptophan and cystin are furnished in the food; animal proteins are relatively rich in these essential amino acids; while many vegetable proteins are deficient in them. Lactalbumin is the one which contains the essential amino acids in largest proportion; casein is especially deficient in cystin, an amino acid which is essential for normal growth to take place. In breast milk lactalbumin constitutes two-thirds of the protein

in the milk, whereas in cows' milk it constitutes only one-fourth of the total protein; it is apparent that artificially fed infants, to obtain the necessary amount of essential amino acids, must take more total protein in the form of cows' milk than a breast fed infant receives.

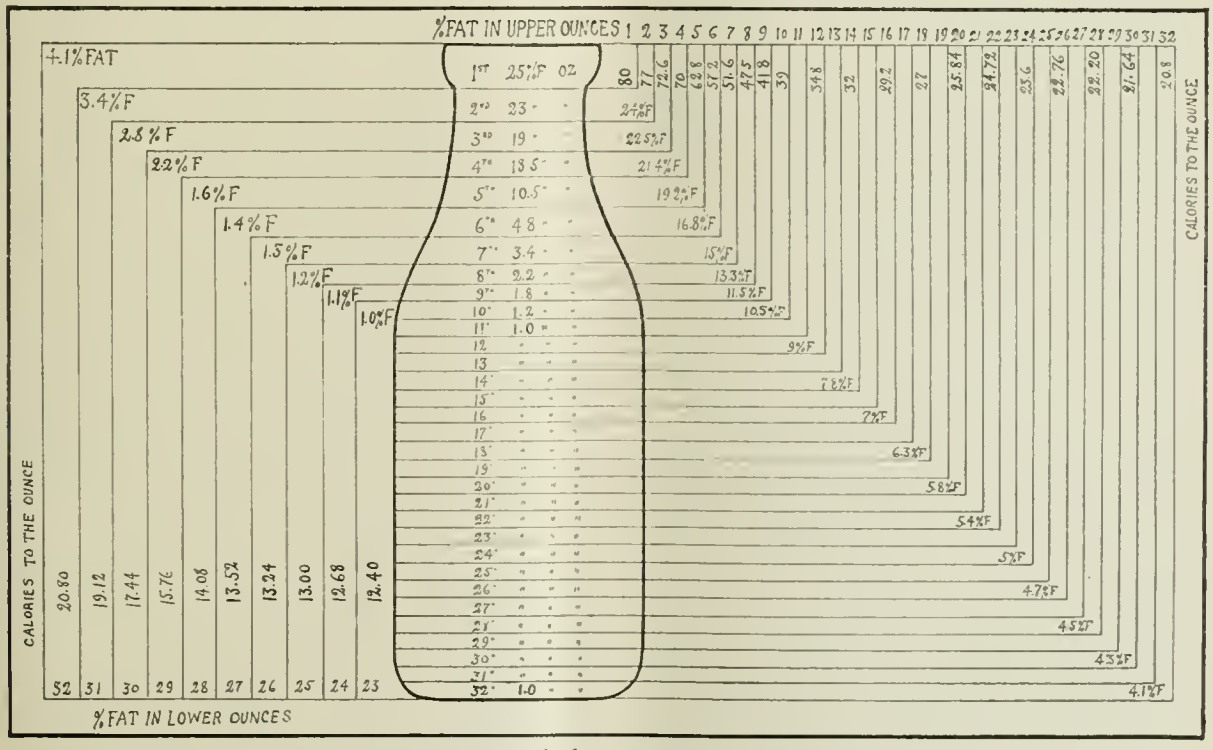
Without carbohydrates in the diet the nutritive functions of a growing individual are menaced quite as readily as during adult life; in the lack of carbohydrates the metabolism exhibits pathologic manifestations. It has been found that no infant can thrive unless it receives about one-sixth of an ounce of carbohydrate to every pound of its body weight.

Conclusive evidence as to whether true fats are an actual requirement for the maintenance of a healthy normal organism is lacking; however milk fat contains something essential for growth, and unless the required amount is supplied no growth can take place. It has been found that the young infant requires about 2½ to 3 ounces of water to every pound of its weight in the first 6 months and about 2 to 2½ ounces in the second 6 months. The smaller the infant is for its age and the less it weighs the greater is the water need. A certain definite amount of salts is necessary for growth; when the amount of salts is deficient neither gain in weight nor growth can take place.

Growth is also dependent on substances which are not identical with the ordinary nutrients and which, despite the minimal amounts thereof present in the diet are nevertheless indispensable for growth and maintenance of life; these substances have been called vitamines; while the vitamines are indispensable no amount of them will induce growth on dietaries in which the proportion and nature of inorganic salts are inappropriate, in which suitable carbohydrate is missing, or the character and the quantity of the protein is inadequate. It is the destruction of these substances through pasteurization and boiling of milk that renders such milk in predisposed infants capable of developing scurvy.

Very often the prescribing of too much of an element leads to definite dangerous symptoms; thus, too much fat in the food may cause constipation, convulsions, ammoniacal diaper, acidosis; too much sugar leads to diarrhea, intoxication, fever, edema; too much protein, to fever, leucocytosis, prostration; too much salts, to intoxication, fever and edema; too much water, to increased loss of protein and salts. The prescribing of too little of these elements has serious drawbacks also; if too little fat is given, rickets is apt to develop; if too little carbohydrates are ordered there will be no gain in weight; when the carbohydrates are entirely withdrawn the by-products of fat metabolism as acetone, diacetic acid and oxybutyric acid, which in the presence of sufficient carbohydrates are burnt to CO_2 and H_2O are excreted as such and cause acidosis; when too little protein is given, the musculature is flabby; anemia is present; the whole physical development is backward; when too little salts are given there is no gain in weight and no growth takes place; when the water supply is insufficient there is no gain in weight and the infant may have "thirst fever."

Composition of the Milk.—Milk contains the following elements: Fat, sugar, protein, salts, water, and vitamines. When milk is coagulated and allowed to stand for half an hour it separates into a thick mass and a fluid portion. The thick mass or curd consists of the fat and the casein of the milk, and a large part of the insoluble salts (Ca, Mg, P_2O_5); the whey or fluid portion contains most of the water (one quart of milk yields 22 ounces of whey), the sugar, the lactalbumin, and most of the soluble salts (Na, K, Cl).



1 level tablespoonful of cane sugar = 60 calories
1 level tablespoonful of milk sugar = 40 calories
1 level tablespoonful of dextrin maltose = 40 calories
1 level tablespoonful of flour = 35 calories

Milk in which the cream and the lower portion are admixed is called whole or mixed milk; cream is milk which contains a high percentage of fat. When cows' milk is put into bottles (immediately after it is drawn and cooled), after 4 hours standing, the upper 8 ounces will contain nearly all of the fat that will rise as cream; by varying the number of ounces which we remove from the top of the bottle of such milk, we obtain different kinds of top milk. Top milk is therefore milk which is obtained from the top of a bottle which had been bottled soon after the milk was drawn, and allowed to stand in the upright position for at least 4 hours; depending on how many ounces from the top of the bottle we remove we have different kinds of top milk (5 per cent. milk to 25 per cent. milk); the figure in each case indicates the percentage of fat in the milk. The layer of cream is not of uniform composition; the greater the number of ounces that are removed from the top the less the percentage of fat in the mixture and vice versa. Top milks which contain more than 16 per cent. of fat are usually known as creams. Cream may be obtained by the gravity process or by means of the centrifugal machine (separator); gravity cream contains from 16 to 20 per cent. fat; rich centrifugal cream contains 30 to 40 per cent. fat.

When top milk is removed the remainder is skim milk; the greater the number of ounces of top milk that are removed the less the percentage of fat in the skim milk; by varying the number of ounces removed from the top we can obtain skim milks which contain 3 per cent. fat, 2 per cent. fat or 1 per cent. fat; as all the fat that rises as cream does so in the top 8 ounces, the percentage of fat in the remainder of the milk (lower 24 ounces) is of uniform composition (1 per cent. fat); it is thus not possible to obtain a skimmed milk of less than 1 per cent. fat by the gravity method; when a fat free milk is desired the fat must be removed by a centrifuge or separator.

The proteins, sugars and salts in top milks, whole milk, and skim milk are approximately the same (proteins 3.5 per cent., sugars 4.5 per cent., salts 0.75 per cent.); slightly less in top milks, except in very rich creams where they are reduced to two-thirds of the original quantities (see chart).

From extensive studies conducted for the last ten years we have come to the conclusion that the great majority of healthy infants thrive better, develop better and undergo a lesser morbidity and mortality when dilution of whole milk are used than from the use of dilutions of top milk. Infants who suffer from fat intolerance should be put on formulas derived from skim milk; those with sugar intolerance, on top milk mixtures or eiweiss (protein) milk; infants who are very much underweight and do not present any intestinal symptoms should be put on skim milk with a high percentage of carbohydrates, because such a mixture contains a low percentage of fat, an element which is the hardest to digest and is most apt to cause indigestion and one which consumes the largest number of calories in its digestion; high percentage of protein, an element which seldom causes any indigestion; and a high percentage of carbohydrates, an element which is the most readily assimilated and with least expenditure of energy; and a high per cent. of salts, which is conducive to a retention of water, as these infants are dehydrated.

About 90 per cent. of all infants do well on whole milk dilutions; in about 7 per cent. it will be necessary to use skim milk mixtures and in about 3 per cent. top milk mixtures. Intolerance for milk as a whole or for any of its elements is the least common cause of malnutrition; for every case of malnutrition due to intolerance there are nine due to over or underfeeding, irregular feeding, improper technique or method of preparation. Of the intolerances, that for fat is most frequent (70 per cent.), for sugar less frequent (20 per cent.), and for protein least frequent (10 per cent.).

In protein indigestion the casein may be removed by the use of whey and the amount of casein in the milk formula may gradually be increased by adding more of the curd to the milk mixture; protein digestion may be facilitated by the use of alkalies (no protein digestion takes place in the stomach in an alkaline medium, we must add 25 to 50 per cent. lime water), by the use of cereal diluents (casein is precipitated in much finer flocculi), by the use of sodium citrate (1 to 1½ grain of sodium citrate to every ounce of milk used—the milk does not curdle under these conditions), by boiling, peptonizing, or homogenization of the milk. In most cases all that is necessary is to bring the milk to a boil, and all the symptoms of protein indigestion usually disappear.

In a small number of cases of fat indigestion improvement may be obtained by homogenizing the milk, by using milk derived from Holstein cows exclusively (such milk contains more olein and less of the volatile glycerides, and these fats appear more digestible and more in accordance with those of human milk) and by using skimmed milk to which washed butter fat has been added (the low volatile fatty acids are soluble in water and can thus be removed).

In severe cases of sugar intolerance it is not possible to reduce the percentage of sugar in the mixture sufficiently by the use of the ordinary mixtures and still supply the desired number of calories in the mixture; in these cases a mixture known as eiweiss or protein* milk must be used; in this mixture the sugars are low and the proteins and the fats are high (F, 3 to 3.2 per cent.; S, 1.5 to 2 per cent.; P, 3 to 3.5 per cent.) It is made by curdling a quart of milk; the whey is discarded; the curd is rubbed through a fine sieve with addition of a pint of buttermilk; a pint of water is added, and the whole mixture (under constant stirring) is brought to a boil; as soon as the symptoms subside sugar is added to the mixture (dextrinmaltose is the sugar of choice in these cases). In cases of sugar intolerance flours are often better

*To those who cannot afford eiweiss milk (30 cents a quart) we suggest the following mixture, made from one quart of milk which costs only 10 cents a quart; it can be used in all cases in which eiweiss milk is indicated: To a half quart of milk add 2 junket tablets; allow to stand for half hour; then strain and discard the whey; the curd is rubbed through a fine sieve into the other half quart of milk; enough plain boiled water is added to make one quart; the whole mixture is now brought to a boil under constant stirring, and is ready for use. The composition is nearly that of eiweiss milk, except that it lacks the acidity of the protein, which does not seem essential.

tolerated than sugars; therefore part of the carbohydrates should always, in these cases, be supplied in the form of flour. When over 7 per cent. of carbohydrates is used in a mixture, part of the carbohydrates should be supplied in the form of flour; and when over 10 per cent. is used a flour and two kinds of sugars (cane and dextrinmaltose) should be used; in this manner infants can tolerate much higher quantities of carbohydrates without being upset.

After we have decided from the history and the symptoms which kind of milk to use (whole, skim, top), the next point to determine is the quantity of food for the 24 hours; thus if an infant weighing 10 pounds at 3 months, is to be put on a formula, we must prescribe 4 ounces every 3 hours with 7 feedings a day, that is 28 ounces for the day; as it is never advisable to prescribe more than 35 calories to the pound in the first formula we must furnish 35 × 10 or 350 calories in the food for the day; if it is a case for whole milk dilutions, we must prescribe 9 ounces of whole milk and 19 ounces of boiled water as diluent (the first formula should never contain more than one-third milk; *i. e.* one part of milk and 2 parts of water);* as 9 ounces of whole milk yield only 180 calories and we must supply 350 calories in the food, we must add 170 calories in the form of additional carbohydrates; we can therefore add two level tablespoonfuls of cane sugar (120 calories) and one level tablespoonful of flour (about 40 calories) or we may add 2¾ level tablespoonfuls of cane sugar.

If from the history and symptoms we decide to use skim milk we must prescribe 1 per cent. skim milk, 14 ounces, and 14 ounces of boiled water as diluent; 14 ounces of 1 per cent. skim milk yield 180 calories; we must therefore supply 170 calories in the form of additional carbohydrates (2¾ level tablespoonfuls of cane sugar, or 4½ of dextrinmaltose or milk sugar, each of which yields about 170 calories).

If it is a case of sugar intolerance, and we wish to supply 350 calories, and we do not wish the sugar to be over 2 per cent., we must use top milk; in this case 10 per cent. milk.; thus if we prescribe 9 ounces of 10 per cent. milk, which yield 360 calories, we do not have to add any additional carbohydrates to supply the necessary number of calories; as diluent we must add 19 ounces of boiled water.

Each of these mixtures contains 360 calories, and each is made up to contain 28 ounces; the difference is in the percentages of the different elements, so prescribed as to meet the different types of indigestion. The percentages of the different mixtures are given in the table which follows.

The best diluent is boiled water; there is absolutely no necessity of adding any adjuvants, as cereal diluents or alkali as a routine, to the infant's milk mixture; it was either to influence the acidity of cows' milk or to modify its curd that they were added; as we know now that breast milk is amphoteric and that the protein of cows' milk but seldom gives rise to any digestive difficulties, there seems to be no rational basis for the routine administration of either cereal diluents or alkalies.

Kind of milk	4 per cent	1 per cent	10 per cent
Number of ounces of milk	9	14	9
Number of ounces of water	19	14	19
Cane sugar in level tablespoonfuls	3	3	0
Quantity at a feed, in ounces, number of feeds	4—7	4—7	4—7
Percentages of fat, sugar, and protein	1.3, 6.5, 1.2	0.5, 7.6, 1.75	3.3, 1.5, 1.2
Calories in the milk	180	180	360
Calories in the sugar	180	180	0
Total number of calories	360	360	360

The quantity to be given at a feeding and the length of the intervals, the number of feedings, and the quantity to be given in the 24 hours have already been considered; after the second month no infant should receive any night feedings; when the infant takes two-thirds milk the intervals should be every 3½ hours and when whole milk is prescribed the intervals should be 4 hours and the number of feedings in the 24 hours should not be more than five. Of the sugars we use a dextrinmaltose preparation in every case, unless there is some contraindication. We usually ordered one level tablespoonful of the sugar to every 10 ounces of the mixture (never exceeded 7 per cent. in healthy infants).

We have found that dextrinmaltose is not well borne by infants under 2 months of age, and that it is contraindicated in cases where there is a tendency to constipation. The more maltose a dextrinmaltose preparation contains the more laxative it is. Dry dextrinmaltose preparations, unlike the fluid preparations, are not laxative but on the contrary when used for a long time and in considerable quantities produce constipation. This sugar is also contraindicated in cases where there is vomiting. It is distinctly indicated in cases where there is a tendency to looseness of the bowels, and its greatest field of application is in babies that are underweight.

Lactose seems to be the most laxative of the sugars and we have often combined the two with great advantage. In early infancy we have mostly used cane sugar, and as the infant grew older we gradually substituted dextrinmaltose for part of the cane sugar. Regardless of which sugar is used, after a time in certain predisposed infants, it tends to constipate; in these we had good results by changing one sugar for another. In cases that could afford to buy it we recommended Loeflund's malt soup; this was substituted for part of the sugar in the formula. This soup almost invariably produced the desired effect on the bowels, although it caused no greater increase in weight than the dry dextrinmaltose preparations. One often hears that in healthy infants we get the same result, no matter which sugar is used. This has not been our experience. Dextrin-maltose causes the greatest gain in weight. cane sugar less, and lactose the least. Their effect on the gastrointestinal tract is also different; lactose has the least and maltose has the greatest tendency to produce vomiting; lactose is the most and dry dextrin-maltose preparations are the least laxative of the sugars.

In the first few days after the infant had been put on a new formula our policy must be one of watchful waiting; the formulas must not be changed

*If milk is indicated at all, it is never necessary to make any greater dilution than one part of milk and two parts of water; even the puniest infant can digest this. If one thinks such dilution may be too strong, it is better to withhold all milk for a day or two, and then begin with one-third dilution.

too frequently and never without any definite reason; our first aim must always be to abate symptoms and to improve the general condition; when this is accomplished we must aim to produce regular and sufficient gain in weight and proper physical development.

When infants are doing well the quantity should be increased an half ounce at a feeding every 2 to 3 weeks; when the quantity is increased the formula should not be strengthened and vice versa; neither too many nor too radical a change should be made at any one time, when the infant is doing well; the total of 42 ounces of fluid should never be exceeded during the first year. No more than one quart of milk should be given in the 24 hours.

The strength of the formula should be increased as the gastrointestinal symptoms and the weight indicate; if an infant has gained sufficiently during a certain period of observation (5 to 8 ounces a week), there is no indication to change the formula; however if the infant has not gained sufficiently, then we must increase the number of ounces of milk in the formula and correspondingly decrease the number of ounces of water in the mixture, one ounce at a time. When the infant receives one quart of milk a day and shows no gain in weight, then we must substitute flour (wheat, barley, or oatmeal boiled in the water of the mixture) for part of the sugar (one tablespoonful at a time); when the infant had been gradually adapted to take 2 to 3 per cent. starch in the milk, it is time to introduce thick gruels in the form of porridge (not to be strained and to be fed with a spoon) to the infant's diet. In healthy infants it is never advisable to raise the sugar above 7 per cent. in the mixture; when the food must be strengthened it is always better to increase the milk (not above 1 quart) than to raise the carbohydrates above 7 per cent. In cases of fat intolerance it is sometimes necessary to raise the sugar to from 10 to 13 per cent.; in these cases part of the carbohydrate must be given in the form of starch, and more than one kind of sugar must be used in the same mixture; in this way we can prescribe a high percentage of carbohydrates without developing an intolerance. No infant should be kept on a mixture containing over 10 per cent. of carbohydrates for any length of time, because such infants usually have a diminished resistance to infection, even though they may be above normal in weight.

When the infant shows loss of weight, it is essential to determine the cause of the loss; insufficient food is only one of the causes; the temperature of such infants should always be taken to exclude possible constitutional disease, especial inquiry should be made about the appetite, gastrointestinal symptoms, sleep, etc.; one must always be sure that the loss is not due to overfeeding, and when the cause is ascertained the infant must be treated accordingly.

Fruit juices (orange juice ½ ounce, prune juice or apple sauce 2 level tablespoonfuls) should be given early (from 2 to 3 months of age) if pasteurized or boiled milk is used. Beef juice or finely mashed yolk of hard boiled egg (hard boiled for 20 to 30 minutes and rubbed through a fine sieve and given with milk from a spoon or put into the whole milk mixture) is ordered at 6 to 7 months; earlier if the infant is anemic (may also use sweet wine of iron to be given in the milk; in very severe anemia, sodium cacodylate and arsenic can be given hypodermically). At 9 months broths (chicken, mutton; later vegetable soups), the vegetables (spinach, peas, beans, carrots) boiled for 3 hours and mashed fine and not strained) can be given. After the sixth month 2 to 3 zwiebach, milk, or arrowroot crackers should be given during the 24 hours.

In cases put on skim milk the method of procedure is as follows; as the infant's food is strengthened we skim less and less from the top of the bottle; as we increase the amount of fat in the mixture we correspondingly decrease the amount of carbohydrates, and the quantity is increased as in normal infants. All changes in infants with any intolerance must be more cautious, more gradual and less radical than in healthy infants.

When top milk is used, because of sugar intolerance, we must gradually increase the percentage of sugar and reduce the percentage of fat in the mixture; this is accomplished by using a mixture which contains less fat. Thus if we began with a 10 per cent. milk, our next change would be to prescribe a 9 per cent. milk and order more sugar and in cases of fat intolerance which had been on 1 per cent. milk our next change would be to order 1½ per cent. milk and to reduce the sugar. In this way we can increase the tolerance for the element for which there is an intolerance and gradually reduce the percentage of the element which had been given in more than normal percentage to make up the necessary number of calories.

One must remember that the food must not only be of proper percentages and calories, but that the amount given at a feeding, the method of administration, preparation, the length of the intervals and the number of feedings, and the hygiene and care of the infant must all be proper and receive careful attention if success is to be desired.

THE SIGNIFICANCE OF ABDOMINAL PAIN.*

By MOSES BEHREND, A.M., M.D.,

PHILADELPHIA.

SURGEON TO THE JEWISH, MOUNT SINAI, AND LEBANON HOSPITALS.

PAIN the universal expression of inflammation and injuries concerns us now more especially in conditions relative to the abdomen. The character of the pain often diagnosticates the location of the lesion; burning and itching pain affects the mucous membranes; sharp and lancinating pain characterizes inflammation of the serous membranes. A throbbing pain is usually the site of confined pus. But pain that suddenly disappears portends gangrene and is a serious signal.

In order to follow a logical sequence in relation to the various organs of the abdomen we divide it into the upper, middle, and lower abdominal regions.

The structure most frequently the seat of pain in the upper abdomen is the gallbladder. This statement is made with the full knowledge that the stomach is included in this region. The character

*Read before The North Branch Phila. County Medical Society, March 26th, 1917.

of the pain in acute gallstone colic is sharp, agonizing, and continuous. The pain often radiates to the back, to the middle of the spinal column, at other times to the middle of the shoulder and down the right arm. In those cases of chronic obstruction of the cystic duct with filling up of the gallbladder with fluid or stones, the pain may be of a continual boring character in the region of the gallbladder or the symptoms may be referred to the stomach and the patient calls it indigestion. It is a remarkable fact that many gallbladders filled with stones and fluid to the bursting point are painless. I have no satisfactory explanation of this phenomenon except that the signs of inflammation are absent. Again in gallbladder trouble there may be a continual burning sensation in the back unaccompanied by any other symptom. In this region may also be found pain as the result of hepatic and subhepatic collections and subdiaphragmatic abscesses secondary to appendicitis, ruptured duodenal and gastric ulcers, and pancreatitis. A few weeks ago I operated on a case of subhepatic abscess or rather a subhepatic collection. Six weeks before the operation the patient had pleurisy. On opening the abdomen several pints of fluid were evacuated. In this case the ascending colon, duodenum, and pylorus were included in the mass adherent to the sac. Two weeks later a mechanical ileus resulted when an anastromosis of the transverse colon with the ileum resulted in the cessation of all further symptoms.

Pain in this region may also be referred one from a pleurisy, a pneumonia, or an acute pneumothorax. Acute pneumothorax must be added to the long list of diseases in making a diagnosis of acute pain in upper abdominal trouble. The patient referred to went to bed perfectly well; at 2 A.M. he was suddenly seized with pain in the chest which was referred to the epigastric and hypochondriac regions. Careful examination revealed the signs of pneumothorax. An *x*-ray by Dr. Manges confirmed the diagnosis.

The next most common condition in this region is gastric or duodenal ulcer. The character of the pain varies a little as to the situation of the ulcer. In duodenal ulcer the pain comes on an hour or two after meals and may awaken the patient in the early morning hours. The pain of duodenal ulcer is relieved usually by the ingestion of food. The situation of pain as to the right or left of the epigastric region really gives little practical information as to the location of the ulcer. In gastric ulcer the pain comes on immediately after eating. The character of this pain varies in different individuals. Usually in these cases indigestion has been complained of for a long time.

One must always be on his guard for a ruptured gastric or duodenal ulcer; the pain here comes on suddenly without previous warning except that there may be a long history of indigestion which may not be elicited without close questioning of the patient. The rupture may be the first symptom for which the patient consults the physician. This actually occurred in a patient on whom I operated about nine months ago. The diagnosis was verified at operation, the opening was closed, and a gastroenterostomy performed. In these cases of rupture there is a gradually spreading peritonitis which gives rise to a spreading pain over the entire abdomen. The abdomen is rigid and the rigidity travels rapidly. There may or may not be any vomiting during the first twelve hours but after this time if the case is unoperated, the pain becomes intensified and all the other signs of a raging peritonitis become more marked. Then persistent vomiting with increasing generalized pain follows. It is a sad commentary on the profession, but too many patients with perforated gastric and duodenal ulcer die because the condition is not recognized early enough.

The pain of pylorospasm may be mistaken for that of a gastric or duodenal ulcer.

Pain that comes on in this area in persons over 40 must always be looked upon with suspicion as the precursor of cancer. This does not mean that every pain in the stomach after the age of 40 is due to cancer. At times pain is the last symptom, which is rather unfortunate from the standpoint of surgical relief. The incidental condition, however, of fair, fat and forty and gallstones must not be forgotten in relation to pain in the region of the stomach.

Recently syphilis of the stomach has received some attention. The symptoms are similar to those of cancer of the stomach.

Pain which is found in those who are neurotic has interested me greatly. I have done many gastrotomies for functional conditions because the symptoms these patients suffer are the same as those with true gastric and duodenal lesions. Upon opening the stomach nothing pathological can be demonstrated but the patients are cured. Surgeons have operated on cases of beginning locomotor ataxia on account of the pain of gastric crises stimulating an organic lesion. I must confess that I am guilty of having performed a gastroenterostomy in an early case of tabes. In this category may be included the pain resulting from Dietl's crises. Pain in Glenard's disease is of an exhausting character. It is continually nagging in character which contributes in no small measure to the inanition found in these cases.

Pain is noted, but not often, in an enlarged spleen found in the anemias. This is usually due to the weight of the organ tugging on the gastrosplenic omentum. Pain may be a constant symptom in perisplenitis and perihepatitis.

The pain of acute pancreatitis is sudden in onset usually found in drinkers and high livers. The patient is very much shocked, he may die suddenly or in the course of a few hours. In the cases that survive the acute symptoms and are not operated upon these may form a large pancreatic cyst which causes pressure pain from overdistention of the sac. In this region the extraperitoneal organs that may be the seat of pain are the kidneys. This may be the result of a stone, inflammation, or a new growth. Pain in stone is usually of a colicky character, beginning in the back but radiating to the front of the abdomen and down the scrotum or penis. There may be some difficulty at times to differentiate gallstone colic from kidney-stone colic. The *x*-ray may be of some assistance but this is not infallible.

In the midabdominal region probably the most frequent condition causing pain is an umbilical hernia, especially when it is incarcerated. Inflammatory conditions about the umbilicus due to a

patulous urachus may give rise to enough skin irritation to cause pain of an annoying character. Then one must not forget Paget's disease and the ordinary epitheliomas that may arise here. In this region pain may arise from new growths of the great omentum and small intestines. A very distressing condition is aneurysm of the abdominal aorta, causing intense and continual boring pain. In caries of the lumbar and dorsal vertebra, the pain is often referred to the ventral region of the abdomen. Two years ago a prominent neurologist treated a case of this character for neurasthenia and a prominent orthopedist diagnosed the case as one of sacroiliac disease. The patient had at the time I examined him all the signs of caries of the spine. The *x*-ray showed a definite focus of necrosis in the lumbar spine. A few weeks later a lumbar abscess was opened which relieved his pain referred to the ventral surface of the abdomen.

Petroperitoneal sarcoma, a very malignant condition, gives rise to an harassing pain which exhausts the individual in a comparatively short time.

When one studies the lower abdomen naturally the right iliac fossa is given first thought. The most common abdominal condition giving rise to pain is inflammation of the vermiform appendix. The pain in appendicitis is characteristic. It comes on suddenly in an apparently well person and it is the first symptom. It is sharp, cramp-like in character, affecting first the entire abdomen, then it centers itself around the umbilicus, and finally localizes itself in the right iliac fossa. The pain continues unless relieved by drugs, nature, or an operation for its removal. Drugs are mentioned only to be condemned. Nature may resolve the inflammation until the next attack, or she may be instrumental in precipitating the much feared condition of gangrene of the appendix. In other words when pain in appendicitis disappears look for gangrene of this organ. A word of admonition seems here in order, namely that as soon as the pain of appendicitis is present it ought to be synonymous with operation.

In the left iliac fossa pain from a diverticulitis is usually accompanied by the signs of inflammation that one would get in appendicitis. The pain and acute inflammatory signs may disappear, but the tenderness and the mass may remain. The sudden acute pain which accompanies perforation in typhoid fever is not seen often at the present time on account of the rarity of this disease in this vicinity.

Pain nauseating in character shooting into either fossa from an enlarged testicle, be it inflammatory or not, must not be confounded with an intra-abdominal condition. This is especially true on the right side where many cases have been wrongly diagnosed, strange to say, as appendicitis.

A condition found on the right side often confounded with acute and even chronic appendicitis is stone in the ureter. Naturally this mistake would not be made on the left side. I have operated on four cases for acute appendicitis when later by *x*-ray a stone in the ureter was found, the symptoms persisting after the operation for the removal of the appendix. This has been a rather common experience with other surgeons also.

A distended bladder reaching to and sometimes beyond the umbilicus gives rise to a peculiar sickening pain which may be accompanied with overflow from retention or a constant desire to urinate. These tumors so-called have been mistaken for a cyst or other abdominal tumor but the catheter easily makes the diagnosis.

The constant straining on urination in an enlarged prostate gives a characteristic pain. It is usually burning in character, very distressing and weakening on account of the loss of sleep occasioned by frequent nocturnal and diurnal urination. The pain may be the result of a mechanical obstruction or an accompanying cystitis or both.

We can dismiss the whole subject of hernia with one word—there is no pain unless strangulation or incarceration is present. Hernia in the young is best treated by operation on account of the brilliant results with practically no mortality.

The differentiation of the pain of mechanical ilieus and that of peritonitis is not always easy. The pain of mechanical ileus is paroxysmal, usually follows operations, and is not accompanied by fever. The pulse is rapid. There may be distention of the abdomen. Peristalsis may be increased.

The pain of peritonitis is persistent and is accompanied with the characteristic facies and bounding pulse. Distention is a prominent symptom and peristalsis is absent. The patient is restless and wakeful and simply cannot sleep. Morphine is powerless unless given in enormous doses. The subsidence of the pain and rigidity is a bad sign as it is indicative of the submission of the patient to the toxemia.

In conclusion pain teaches us that we must be alert, that it is nature's danger signal for prompt action, that we must read the signs correctly, that prompt surgical interference will save more lives than procrastination.

1427 North Broad Street.

BRONCHIAL ASTHMA.

By M. FORD MORRIS, JR., M.D.,

CHELSEA, MASS.

RESIDENT PHYSICIAN, SOLDIERS' HOME IN MASSACHUSETTS.

Bronchial asthma has been defined as "a spasmodic or paroxysmal dyspnea which is the direct result of a stenosis of bronchi"[1]; as "an affection characterized pathologically by a spasm of the bronchi and of the respiratory muscles, and by vasomotor disturbances of the bronchial mucous membrane"[2]; as "a congenital sensitiveness to certain foreign proteins."[3]

Etiology.—This disease is sometimes inherited. Males are said to be affected twice as often as females. Diseases of the respiratory mucous membrane, especially catarrhal conditions of the nasal passages, are of frequent occurrence before the development of asthma. According to J. Matthews,[5] in over 90 per cent. of 300 cases treated in the Mayo Clinic, the principle lesions which might be considered etiological were in the upper respiratory tract, chronic suppuration or the retention of mucoid secretions in the nose or accessory sinuses occurring in the majority of cases. Enlarged tonsils, nasal polypi, certain odors, change of air, gastric derangement, intestinal worms, and uterine disease have been mentioned as predisposing causes. Emotional disturbances and psychical impressions may be ex-

citing causes. By many this disease is regarded as a neurosis.

"The cause may be one protein or several proteins, the most common of which are those of pollen, horse-dust, feathers, etc. When the causative protein is injected subcutaneously, a reaction, similar to that of Schick in diphtheria, is obtained. In this manner the exact cause or causes may be ascertained. In other words, an asthmatic attack is an anaphylactic paroxysm."[3] Billings[4] reminds us that in man the phenomena of anaphylaxis may be asthma, hypoarterial tension, eosinophilia, and urticaria; and that adrenalin and atropine administered hypodermatically tend to relieve anaphylactic shock and also to relieve clinical bronchial asthma.

Into laboratory animals Oftedal[6] injected intravenously varying amounts of twenty-four-hour cultures taken from persons suffering with bronchial asthma. A few of these animlas died of an overwhelming septicemia, but the survivors presented, within 24 hours, real dyspnea, and over their chest wheezing and râles could be heard. At autopsy were found gross and microscopical emphysema and engorgement of the pulmonary blood vessels, with considerable round-cell infiltration; the bronchioles were contracted as if in spasm, and the mucosa was thrown into folds which almost obliterated the lumen. Streptococci were found in the bronchial musculature. In nearly every case the blood and other body fluids and all organs except the lungs were found to be sterile, while the lungs yielded a pure culture of the hemolyzing and green-producing streptococci, while in one case a pure culture of *Streptococcus mucosus* was obtained from the lung tissue. After a study of these results and of clinical histories, Oftedal concludes that at least a large number of persons suffering with bronchial asthma have, in their sputum, organisms (streptococci) which have an affinity for bronchial musculature, and that the invasion of the lungs of these organisms, when made possible by any factor, psychic or otherwise, which tends to lower the resistance of the individual, will bring about a tonic spasm of the bronchial muscles and cause the typical phenomena in a clinical attack of asthma.

Eustis[7] refers to work which has shown that the Charcot-Leyden crystals found in asthma are amins, similar to cadaverin and putrescin, and the result of putrefaction of proteins. Also Barger and Dale, while attempting to isolate the active principle of ergot, obtained a base, betaimidazolylethylamin, which was found to produce contraction of the musculature of the bronchioles. A similar substance was obtained by the putrefaction of histidin (an amino acid formed in the normal peptolytic digestion of proteins). This base has been used to produce experimental asthma. In other words, by the putrefaction of histidin taken in the proteins of a diet, this same base, betaimidazolylethylamin, is produced and absorbed in sufficient quantities to produce asthma. This author also refers to the connection between pus pockets and asthma, and says it is rational to assume that the absorption of some poison from the intestinal tract, alveolar abscess cavity, or ethmoid cells is followed by the rendering inert of such poison, while in other individuals who are unable to detoxicate this poison, the absorption of such substance is productive of asthma. He explains the fact that certain individuals "outgrow" their asthma by the assumption that these persons develop a tolerance of, or resistance to, this poison.

Pathology.—Although there is some diversity of opinion as to the etiology of asthma, it is generally admitted that, in some way, there is produced a narrowing of the smaller bronchi. Various theories have been advanced to account for the production of the paroxysms, to explain the cause of the bronchial narrowing.

The most widely accepted theory, first advanced by Williams, attributes the paroxysm to spasm of the circular muscular fibers of the bronchial wall. Another theory attributes the paroxysm to swelling of the mucous membrane of the bronchioles, from congestion either of vasomotor or inflammatory origin, the "fluxionary hyperaemia" (of Traube), the "swelling analogous to urticaria" (of Clark), the "vasomotor turgescence" (of Weber), the "bronchiolitis exudativa" (of Curschmann). Still another theory attributes the paroxysm to spasm of the diaphragm, the inspiratory muscles, or both.

The supposition that in asthma a neurosis permits of the reflection of peripheral irritation, usually in some part of the respiratory tract, through the vagus to the circular muscle fibers in the walls of the bronchi, and, sometimes in addition, as a result of vasomotor influences, producing hyperaemia and swelling of the mucous membrane, seems a reasonable explanation of the mechanism of a paroxysm. Depending upon the source of this irritation, pronounced dyspnea is sometimes referred to as "cardiac asthma," "renal asthma." However, the source of this reflex irritation can not always be discovered.

Morbid Anatomy.—As there is on record probably no report of an autopsy done on a patient who died during an asthmatic attack, the characteristic appearance of the respiratory apparatus during a paroxysm is not known. No constant lesion has been found, and most of the lesions are secondary in character. There are usually found the morbid states peculiar to bronchitis and emphysema. However, "autopsies made on animals dead of anaphylactic shock show the alveoli dilated as the result of spasm of the bronchioles."[1]

Prognosis.—So far as a fatal result is concerned, the prognosis is good, no death being on record. Not so long ago asthma was considered as an incurable disease; but now the outlook grows brighter and brighter all the time.

Symptoms and Signs.—Clinically, true asthma has three prominent characteristics: (1) The attacks are paroxysmal in character and are sometimes even periodical, like epilepsy or migraine; (2) the dyspnea is chiefly expiratory; and (3) during a paroxysm the respiratory mucous membranes become hypersecretory. Between attacks the typical asthmatic seems to be in good health. The paroxysm is usually sudden in onset and frequently begins soon after midnight. Trousseau's attacks commenced as the clock struck three. The attacks may last for minutes, hours, or days. There may be prodromal symptoms, such as general uneasiness, thoracic discomfort—"tightness in the chest," sneezing, coughing, a "ball of fire in the stomach," etc.—asthmatic aura.

The patient experiences a sense of suffocation and immediately assumes one of several postures—the one which he has found by experience to aid most in carrying on respiration. With the chest fixed in the position of deep inspiration, the patient uses all the auxiliary respiratory muscles. The dyspnea is mainly expiratory. Expiration is prolonged and associated with wheezing. A copious flow of nasal secretion provokes sneezing. A clammy sweat breaks out, and the extremities become cold. The face is anxious and pale, often cyanotic. The pulse is usually increased in rate and small in volume. The respiratory rate is rarely increased and is often decreased. The temperature is normal, or subnormal. The speech is gasping and trembling in quality. Some authorities (*e.g.* McPhedran) say that cough is not a prominent symptom. The author remembers a case, however, in which coughing was exceedingly severe, often producing emesis.

The sputum of a true asthmatic attack is quite characteristic. Early in the attack it is scanty and tenacious. Later it becomes abundant and mucopurulent. The sputum, which may be blood tinged, consists of grayish-white, semi-transparent, tenancious pellets or perls composed of dense mucus and usually arranged in a twisted manner—the so-called Curschmann spirals—and contain the Charcot-Leyden crystals, degenerated epithelial cells, leucocytes which are mostly eosinophiles, in a medium of thin mucus. These spirals appear early in the attack and disappear when the sputum becomes abundant. The Charcot-Leyden crystals are colorless octahedra and result from the putrefaction of proteins. The spirals are believed to be spirally wound casts of the bronchioles and are thought to be due to acute bronchiolitis,[5] whereas the crystals are thought by some to be the exciting cause of the asthmatic attack.

In the blood, during an attack, there is pronounced eosinophilia.

The oxygen in the expired air of a normal individual is, in the asthmatic, almost or entirely replaced by carbon dioxide.

On inspection, the chest is greatly distended, very little thoracic movement occurring. The abdomen is usually full. On percussion, the hyperresonant note of emphysema is obtained. The area of liver dullness is reduced, and the cardiac dullness is greatly depressed. By palpation, rhoncal fremitus is detected; vocal fremitus is decreased. On auscultation, squeaks and groans are heard over the entire chest, and often râles may be heard 20 to 30 feet away.

Treatment.—A physician should not wait until his patient is in the throes of a paroxysm before instituting treatment. A very thorough examination should be made, and, if the cause is ascertained, it should be removed if possible. Every abnormality should be remedied. Sleeping in the open air, bathing in cool water each morning and then rubbing the body briskly with alcohol, and wearing moderately light-weight clothes, with wraps of sufficient warmth to protect the individual when out of doors, are very beneficial. Tonics, such as iron, arsenic, the hypophosphites, etc., are helpful. A prescription of Dr. Rufus Dorsey of Atlanta, which the author has used with much success in warding off paroxysms is as follows: Iodi (crystals) gr. 5, Spt. chloroformi oz. i, Spt. ætheris comp. oz. 1½, Alcoholis, qs. ad oz. 3. M. Sig. Teaspoonful in glass of cold water every 4 to 6 hours. In some cases a change of climate is beneficial; in others, injurious. The diet should be of moderate amount, of high caloric value, and low in proteins. Special care should be taken to secure good elimination. There are hopes that soon we may immunize patients against the causative protein or proteins. Good results from repeated injections of serum have been reported by Widal, Lermoyez, Abrami, and others. Like results have been obtained by the use of phylacogens and autogenous vaccines by Babcock, and Koessler, and Moody. Lately, Rogers[9] of Calcutta has reported excellent results from the use of autogenous vaccine (the organisms in which were usually pneumococci and streptococci) prepared from a culture of sputum.

To relieve a paroxysm, each of the following agents is useful: (1) Nitroglycerin, gr. 1/100; (2) Adrenalin chloride (1-1000 sol.) gtts. 10-15 subcutaneously; (3) Atropine, gr. 1/100 hypodermically; (4) Morphine, gr. 1/4 by hypo; (5) Hysocine, gr. 1/200, and Atropine, gr. 1/100. In old people especially, nitroglycerin should be given with adrenalin, to control the blood pressure. Morphine is probably the most efficacious drug, but it should be given only when other remedies are not available, 1/4 gr. usually being sufficient; however, a dose of two grains was often necessary to relieve a very stubborn case under the care of the author. A mixture of morphine, nitroglycerin, and adrenalin seems to be more effective than either one used singly. Also inhalations of chloroform, ether, and amyl nitrite are very good. Oxygen is also used by inhalation. The fumes of burning Stramonium and nitre paper are good. The patient may smoke stramonium cigarettes. In papaverine, an opium alkaloid of the iso-quinoline group, an excellent drug for the treatment of asthma is at hand, because it distinctly stimulates respiration and dilates the bronchi, and has efficiently relieved asthma of the bronchial type.

Joint Affections and Conjunctivitis in Dysenteric Subjects.—Rist in the course of treating numerous cases of bacillary dysentery noted as an early sequel after recovery vague joint affections of brief duration. These did not respond to the salicylates, but yielded promptly to antidysenteric serum. Somewhat more rare was a conjunctivitis following recovery from dysentery.—*Journal de médecine et de chirurgie pratiques.*

COURSE, SYMPTOMS, AND TREATMENT OF PROCTITIS.

By ARTHUR A. LANDSMAN, M.D.,

NEW YORK.

ASSISTANT, DEPARTMENT RECTAL SURGERY, POST GRADUATE MEDICAL SCHOOL AND HOSPITAL; DEPUTY SURGEON RECTAL DISEASES, O. P. D., NEW YORK HOSPITAL; ATTENDING HOME DAUGHTERS OF JACOB.

Proctitis is an inflammation of the rectum, which may be either acute or chronic, catarrhal or ulcerative, diffuse or circumscribed, atrophic or hypertrophic, simple or specific. The last-named is further subdivided into the amebic, tuberculous, gonorrheal, syphilitic, bacillary, diphtheritic, and erysipelatous, depending upon the causative agent. It should be borne in mind, however, that as the physiological functions of all parts of the colon are closely related, and the histological structure shows no abrupt change, the process is not to be taken as remaining strictly limited to the rectum, but may show involvement of the large, and in some instances even the small intestine. It may begin as an acute catarrhal inflammation, with congestion and slight swelling of the mucous membrane, increased production of mucus, and superficial desquamation of the epithelium, run its course in a few days, and result in complete restitution, or pass from the ordinary mild catarrhal inflammation by gradual stages into the hypertrophic form, characterized by definite changes in the gross appearance and microscopical anatomy of the gut. In gross appearance the mucous membrane is changed from a light salmon-pink to a brick-red or dusky color, becomes granular, roughened, pitted, and spongy, looks swollen and edematous, and feels thickened and relaxed. It is thrown into numerous folds, which readily fall into the lumen of the proctoscope, interfere with proper inflation, ooze an abundance of mucus, and present microscopically a great increase in the intertubular substance. In the last stages the stroma between the intestinal glands has become shrunken and atrophied, the follicles of Lieberkühn flattened and compressed, and the goblet cells destroyed; in consequence the mucous secreting surface loses its succulence, becomes dry, cracked, and fissured, bleeds easily on touch, and is smeared with pieces of dried mucus and strings of gluey material mixed with blood. The process has reached the atrophic stage, in which there are permanent anatomical changes, and complete restitution is no longer possible. If treatment is not begun, or the severity of the infection cannot be controlled, there is interference with nutrition from the toxemia and from the mechanical blocking of the blood-vessels, multiple erosions make their appearance, at first scattered, later becoming confluent, superficial ulceration takes place which becomes deeper from infection and lack of proper drainage, and there is successive involvement of the mucous, submucous, muscular, and fascial coats, and even the serosa when the inflammation is in a part of the gut covered with peritoneum. There is a purulent discharge from secondary infection, free hemorrhage from involvement of the blood-vessels, polypoid excrescences from irritation of the glandular elements, periproctitis or colitis with adhesions, abscess, fistula, and even perforation of the gut. In the end the lumen of the tube becomes irregular, with dilatation here and contraction there, stricture and more or less obstruction with the fecal current. Such is the picture of one of the most formidable diseases with which the proctologist has to deal—formidable because of its wide prevalence, the insidiousness with which it steals upon its victim, its progressive character, and its chronicity and resistance to cure.

Its wide prevalence may be measured by the record of 500 consecutive rectal patients examined in private and hospital practice. These included 273 males and 227 females, 42 per cent. of which were found to have proctitis, either alone or in conjunction with other rectal diseases.

Its vague, indefinite, and obscure manifestations may be best studied by a reference to a few typical cases taken from the records:

Case I.—C. G., confectioner, referred by Dr. R., complains of a persistent, dull, heavy, dragging sensation in the lower back since one year, a feeling of soreness and aching in the pelvis, fullness in the perineum, radiating pain in the left leg and heel, gastrointestinal unrest, occasional discharge of strings of mucus from the bowel, weakness, and inability for sustained physical and mental effort. No constipation, bleeding from the rectum, or loss of weight. Roentgenographic findings of the gastrointestinal tract are negative. Examination of the kidneys, heart, lungs, genito-urinary system, and blood gives negative results. Gonorrhea ten years ago. Proctoscopic examination shows evidence of marked chronic atrophic catarrh with local ulceration. Under treatment five months with topical application to the bowel and irrigation. Improved sufficiently to be able to resume his usual occupation, with but an occasional bad day.

Case II.—M. S., clerk, 25, referred by Dr. S., for a persistent pruritus ani lasting three years. Is constipated, neurotic, sleepless, has dysuria, and has lost some weight. Blood pressure normal, no glycosuria, no genitourinary disease. Operated upon in a general hospital one year ago for hemorrhoids in an effort to relieve his pruritus, but with only temporary improvement. Proctoscopic examination shows chronic hypertrophic proctitis, with gray, localized, atrophic patches, and pinpoint ulcerations. Under treatment for six months with irrigation of the bowel and topical application of 25 per cent argyrol through the proctoscope. Entirely relieved of his pruritus; marked improvement in general condition.

Case III.—R. B., referred by Dr. H., with a history of illness dating back ten years. All examinations negative. Venereal denied. Chief complaints: pain in the region of left kidney and ureter, constipation, nausea, flatulence, headache and backache, occasional bleeding from the rectum. Proctoscopic examination shows chronic atrophic proctitis with ulceration and fibrous stricture of the anal canal. Proctotomy followed by dilatation with Wales bougies and local medication. Generally much improved, constipation relieved, patient able to return to work.

As may be gathered from the above, symptoms which are misleading, and subjective sensations which point to other organs, or do not point definitely to any organ, are the rule rather than the exception in chronic proctitis; only a careful examination of the anus, rectum, and pelvic colon will enable us to assign them their proper place.

Enlightened medical opinion will no longer tolerate the treatment of symptoms when it is possible to locate the cause of the disease; hence those which are thought to be responsible for chronic proctitis have been carefully studied; they may be summarized in the statement that the lesions are due to infection following interference with the nutrition and function of the parts from mechanical, biochemical, or toxic causes.

Any chronic, long-continued irritation from with-

in or without, which reduces the resistance of the parts and lessens their vitality, prepares a suitable soil and invites bacterial invasion. Whether found in its simple or specific forms, the progress of the disease is always the result of infection, which can be resisted by the tissues only so long as the integrity of the mucous membrane is maintained. It further appears probable that in addition to this protective agency there is present in the intestinal mucosa or in the blood-stream some bactericidal substance which is inimical to the life and growth of the myriads of microorganisms which inhabit the intestinal tube; indeed, the fact that human excrement is composed of 33 per cent. of bacteria, and that these are *mostly dead* when the feces are discharged, seems to support this assertion. Examples of a similar protective mechanism are not lacking in the animal economy: normal gastric mucosa is unaffected by the HCl of the gastric juice, and the vesical wall either neutralizes or prevents the absorption of toxic substances from the urine.

Possibilities for infection are constantly present in the gastrointestinal tract because of its peculiar function, the condition of its contents, and its architectural construction. To this we might add ill-effects of unsuitable environment, unhealthful occupations, and vicious habits, which predispose the individual to disease, when they do not directly cause it.

In order that the maximum of nutriment may be absorbed from the food, and that prolonged contact with the absorbing surface may be assured, the fecal current is slowed in the terminal part of the gut. This is favored by anatomical conditions of the intestine, the semisolid character of the fecal matter which does not lend itself to rapid progression, the storage of the undigested residue for a greater or lesser time, and periodic evacuations rather than constant propulsion. It is needless to state that these factors have a tendency to expose the lining membrane to injury and infection. In certain situations of the distal colon there is a change in caliber due to kinking or narrowing of the tube. This is notably true of the rectocolonic junction, where a freely movable portion with a long mesentery is attached to a fixed part which has no mesentery; the former falls over the latter and results in a physiologic folding-over of the gut, whose caliber at that point is further diminished by an increase in the circular muscular fibers (O'Beirne's sphincter) which serves to stiffen the intestinal wall and keep it open. Still another point of narrowing is in the passage of the rectum through the pelvic diaphragm; here the tube makes a sharp bend posteriorly and becomes strongly contracted on account of the arrangement of the circular muscle fibers which surround it to form the internal sphincter, and narrowed by being clamped between the two halves of the levator ani. At these situations the intestine is exposed to constant trauma due to friction, and to liability of ulceration, especially in persons who suffer from chronic constipation, in whom the feces are hard and dry, and expelled only after considerable straining. Straining as a cause of chronic catarrh of the bowel is a factor in prolapse, chronic invagination of one part into another, hemorrhoids, polypi, tumors, fistula, and other rectal diseases; in the presence of intestinal parasites and other foreign bodies, and in the frequent use of drastic purgatives and enemata.

Pressure arising from without is responsible for those cases which originate from a pregnant, subinvoluted, or retroverted uterus, tumors, connected with the adnexa or pelvic wall, hypertrophy of the prostate, stone in the bladder, in short, anything which causes long-continued irritation by pressing on the parts.

Proctitis from specific poisons is found to occur in amebic and other forms of dysentery, tuberculosis, gonorrhea, and syphilis. A considerable number of cases is indirectly due to gonorrhea, in which prostatic massage is a part of the treatment, and is carried out too often, too long, or too vigorously. It may be of interest to mention in this connection that in the series quoted, six patients with severe ulcerative coloproctitis gave a history of habitual anal coitus.

Chronic proctitis is seen in greater or lesser degree in constitutional states such as are present in nephritic, hepatic, pulmonary, and cardiovascular disease, where it is presumably only a part of the general congestion; in diabetes, gout, rheumatism, and in chronic poisoning from alcohol, lead, arsenic and mercury.

A disease which has such a definite and clear-cut pathology ought to present symptoms which are unmistakable, but this is true of only the acute and ulcerative types; hence these forms must be considered separately. Acute proctitis is apt to come on suddenly, possibly after exposure to wet or cold, ingestion of some suspicious article of food, or a change in the milk and water to which one is accustomed, as when city dwellers migrate into the country. The patient complains of gastrointestinal uneasiness, colicky pain in the abdomen, the passage of several soft or watery stools in quick succession, accompanied by a large amount of flatus, tenesmus, griping, frequent and unsatisfied desire to go to stool, discharge of mucus, and perhaps a little blood. The symptoms last two or three days, and end either in restoration to normal or, if the process is a severe one, the establishment of ulceration and secondary infection, with free discharge of pus and blood, abdominal distention, tenderness, weakness, fever, and other general manifestations. Or what is more common, there is improvement for a time, followed by occasional relapses, less severe than the original infection, and the process has become chronic.

The symptoms of chronic proctitis depend upon the type of the disease and its stage. In the hypertrophic form, which is the one most often succeeding the acute, there is apt to be diarrhea or irregular stools, burning in the rectum, tenesmus, frequent desire to empty the bowel, discharge of mucus, sometimes blood, pain and tenderness along the course of the descending colon. Examination of the bowel shows congestion, swelling, and edema of the mucous membrane, which loses its smoothness, is thrown into folds and wrinkles, and appears granular, roughened, and spongy, with superficial erosions or desquamated areas. The parts are relaxed, moist, show a tendency to vegetative excrescences, condylomata, connective tissue tabs and eczematous lesions. This form is likely to follow the acute type and involve higher portions of the gut, in contradistinction to the atrophic, which fre-

quently begins as such, but does not often extend above the pelvic colon. The symptoms of the latter are slow in development, vague and indefinite in course, onset, and duration, and aside from the constipation, point only indirectly to the bowel as the seat of the disease. Both patient and physician are likely to attribute to the latter the heavy, dull, dragging sensation in the pelvis, the fullness and heat in the perineum, the headache and sacral pains, the neurasthenia, the weakness, indisposition, and general unfitness to do the day's work. When purgatives or enemata are used the patient feels worse, in fact, he is less uncomfortable when the bowels are locked up. On proctoscopic examination the parts are found to be dry, have a glistening, polished appearance, thin and parchment-like in spots, show inspissated feces and strings of dried mucus on the walls and valves, and a tendency to denudation of the mucous membrane. As the process becomes more advanced, ulceration is more marked and affects the deeper portion of the rectal wall, the muscular coat, and even the fascial investment, with the possible development of polyposis, intramural abscess, fistula, and periproctitis. There is an exhausting diarrhea, with free discharge of pus and blood, almost constant tenesmus, intestinal colic, flatulence, weakness, anemia, rapid loss of weight, and if unrelieved, a condition of extreme gravity. There is no longer any doubt of the diagnosis when the disease has reached the ulcerative stage.

It must be quite evident from what has been written above that no routine treatment will fit all types of the disease, or be successful in the various stages of it; intelligent handling of the problem must take into consideration the form of the infection, the stage of the disease, and the needs of the particular patient. Its recognition need present no difficulties if we but learn to train our senses, and examine that portion of the large intestine which is within reach of our diagnostic methods.

The acute types of proctitis are pretty generally only a part of a diffuse inflammation of the entire gastrointestinal tract, and as they are dependent on a toxic or mechanical basis, the indications are to remove the cause, get rid of the poison, neutralize its effects, and combat the symptoms. Any laxative may be used which will accomplish the purpose without any undue irritation; compound cathartic pills, senna, aloes, gamboge, and other resinous drugs exert their principal effects on the large intestine, cause congestion of the mucosa, and hence are contraindicated. To neutralize the toxins and replace loss of water and albuminous constituents we give white of egg in water, flaxseed tea, strained cereal soups, and mucilaginous drinks. Olive oil and milk in limited quantities are useful, but liable to induce intestinal unrest. To quiet peristalsis we administer opium by mouth, apply hot fomentations to the abdomen, and irrigate the rectum with warm saline solution by means of a return flow catheter. As the acute symptoms diminish, astringent injections of 1 per cent. zinc and alum, 2 per cent. nitrate of silver, or 25 per cent. argyrol will prove useful. When there is much tenesmus enemata of tincture of opium in starch water may be employed, but suppositories are interdicted, because of their liability to increase the straining.

The treatment of chronic proctitis is directed to the removal of the cause, whenever this is possible, followed by such measures as will prevent further damage, tend to restore the integrity of the bowel, increase the patient's resistance, and make his lot more comfortable. Whether it is found to have its origin in some specific infection, as syphilis or gonorrhea, or in some mechanical factor such as malposition of the uterus, tumors of the adnexa, hypertrophied prostrate, etc., these should receive appropriate attention. Habits which induce chronic constipation or fecal impaction must be overcome by suitable hygienic, dietetic, and medicinal measures. When the patient's illness is secondary to diabetes, gout, cirrhosis of the liver, rheumatism, etc., or to chronic poisoning by lead, arsenic, or mercury, his proctitis is only the local expression of his constitutional condition, and must be considered in whatever is done for him; but no measures may be expected to be successful unless they are reenforced by suitable local treatment of the bowel.

Another point may be set down as axiomatic: drugs, or their solutions, taken by mouth, have little influence on pathological processes within the rectum; they are so greatly diluted by the intestinal contents, and such minute quantities can actually reach the lesions, that it must be doubted whether they can do any good at all, given this way. Moreover, the diseased tissues may be covered with feces or mucus, and not come in contact with the medicine. To obtain the maximum effect of any agent we use, the bowel must be well flushed, and the medicine introduced from below directly to the seat of the trouble. Medicines taken by mouth are often decomposed by the gastric and intestinal juices, or split into their constituent elements by processes of metabolism, so that we cannot even be certain whether we are getting the effects of a given drug. To use medicinal substances by rectum, we have a choice of direct application, insufflation, irrigation, injection, introduction of ointments and suppositories. The two latter methods have not come into general use among proctologists, because they will reach only limited portions of the intestinal tract, and because of their liability to cause straining and irritation. Insufflation has been objected to, as the powders have a tendency to cake on the valves and give rise to griping and proctospasm. Direct application, injection, and irrigation, properly carried out, offer the greatest field of usefulness, no matter what drugs are used. In the hypertrophic form, in which, it will be remembered, the parts are bathed in a free secretion, irrigation with 1 per cent. solution of zinc and alum, 2 per cent. tannic acid, 10 per cent. fluid extract of krameria, 2 per cent. ichthyol, and application through the proctoscope of 5 per cent. silver nitrate or 20 per cent. argyrol to the patches are followed by good results.

In atrophic catarrh conditions are quite unlike what one finds in the hypertrophic form; the mucous membrane is dry, thinned, and fissured, and the stools are irregular, costive, and expelled only after much straining. Our first care should be to correct this condition by a suitable diet, and, if necessary, the administration of bland laxatives, to be followed by injection into the bowel of iodoform, bismuth and olive oil, or balsam of Peru in castor oil, 5 per cent. ichthyol in glycerin, or 10 per cent. silver nitrate applied through the proctoscope.

The trouble in handling these cases arises not from the use of the wrong medicine, but rather from the difficulty, whatever is used, in reaching every part of the diseased bowel. Our duty is not ended when we give the patient a bottle of medicine and tell him to inject it into his rectum; if the patient is to derive any benefit from it, the physician must himself carry out the treatment, or at least supervise it. Solutions injected into the lower bowel may under exceptional circumstances be carried into the colon, but this is entirely too uncertain to be depended upon as a routine measure, especially in the case of some of the drugs, of which limited quantities are available for dispensary, and for that matter for private patients. It was formerly taught that medicinal agents may readily be thrown into the upper bowel by means of a soft-rubber colon tube, but careful experiments, checked by *x*-ray findings, prove this to be erroneous, because of the coiling of the tube within the rectum, and the shutting off of the flow. A simple method, with some modifications which will form the subject of a future communication, has been used by the author during the past year; it is only necessary to state at present that the medicine is poured into the rectum through a proctoscope, with the patient in the inverted position. Gravity will do the rest. Our experience with this method has been very good; we are convinced that it will do the work, because as soon as we begin the treatment of proctitis according to this technique, most of the mild and moderately severe cases improve very quickly; and we have been doing this at the rectal clinic of the New York Hospital for a year. The only reason why the old way has not been discarded long ago, is because it is human nature to follow lines of least resistance, and it is certainly less trouble to hand the patient a prescription or a bottle of medicine; though it is but fair to say that new methods are sure to be generally adopted when physicians discover what good results may be had at the expense of but little extra effort. The pain and discomfort diminish, the burning in the rectum and the pruritus are lessened, the intestinal symptoms improve, the patients gain in weight, and are soon able to return to work.

Finally, we see a certain number of cases in which the predominating lesions are in the upper portions of the colon, properly classified as chronic ulcerative coloproctitis, which are not amenable to conservative treatment no matter how patient, skillful, or prolonged; these have extensive and deep ulcerative lesions throughout the whole of the large intestine, and require surgical treatment in the form of appendicostomy or cecostomy; this enables the surgeon to do through-and-through irrigation as many times daily as necessary, and has the effect of clearing the intestinal tract, removing mucus, pus, bacteria, and products of decomposition, stimulating circulation, reducing autointoxication, and preventing reinfection. The author had the privilege of observing ten of these patients in the rectal service of one of the hospitals, during the past year. Two of these occurred in men under thirty, former residents of the tropics, ill five years, with 10 or more movements of the bowels in 24 hours, containing blood and pus; they had ulcerations of the colon and rectum, and lost between 30 and 40 pounds in weight. No amebæ were found in their stools. Both were operated upon for appendicostomy, were irrigated from above with various solutions, regained their former weight, and made complete recoveries. One of the ten was a youth of 16, who was admitted into the hospital in a serious condition from severe intestinal hemorrhages which reduced his hemoglobin to 20 per cent., and necessitated transfusion; appendicostomy gave him no relief, and as he was fast losing ground, his surgeon performed a total colectomy, and an ileosigmoidostomy in a last effort to save his life. He recovered, gained 60 pounds in weight, and is back at his work.

In concluding, the author would like to emphasize the following points:

1. Proctitis is a very common disease, widely prevalent and often unrecognized, because of its indefinite manifestations.

2. The symptoms of the chronic forms are vague and obscure, and point to the rectum only indirectly, hence proctoscopic examination should be a routine measure whenever the diagnosis is in doubt.

3. Every case of proctitis has potential possibilities of ulceration and stricture, therefore prophylactic treatment of stricture must begin with early and vigorous treatment of proctitis.

4. The cause must be looked for, but whether discovered or not, local treatment of the rectum is the next most important indication, which should not be entrusted to the patient, but must be carried out by the medical attendant.

17 East Thirty-eighth Street.

Medicolegal Notes.

Physician's Compensation Under Workmen's Compensation Act.—The Indiana Appellate Court holds that an employer's direction to a physician to take an injured employee to the hospital, give him close attention, and "do the best you can for him," coupled with the serious nature of the injury, severe third degree burns over the face, hands, chest and hands, and the employer's knowledge thereof, was sufficient to warrant the inference that the physician was authorized to treat the employee beyond the thirty-day period specified in the Workmen's Compensation Act, rendering the employer liable for reasonable charges.—In re Myers, 116 N. E. 314.

Safeguarding Patient in Sanatorium.—The New York Appellate Division holds that it is the duty of the owner of a sanatorium conducted for private gain to use reasonable care and diligence, not only in treating, but in safeguarding, a patient, measured by the capacity of the patient to provide for his own safety, and to discharge such duty, physicians and nurses possessing that reasonable degree of learning and skill ordinarily possessed by persons similarly engaged must be employed, and they must act with reasonable care and diligence. In an action against a hospital and its proprietor for death of a patient, who jumped out of a window under the influence of alcoholic delusions, as it was claimed, the question whether the physician or the nurse should not, in the exercise of the requisite skill and care, have foreseen the casualty and protected the patient from the unguarded window in the bathroom was held to be for the jury.

Judgment against both the corporate and the individual defendant could not stand, because the physicians and the nurse, whose negligence was charged, were not the servants of both; the corporation operated the hospital or it did not, and if it did it was liable, but if it did not, and the individual defendant was the actual operator and master, there was no necessity for judgment against the company. Judgment for the plaintiff was therefore reversed.—Robertson v. Charles B. Towns Hospital, 165 N. Y. Supp. 17.

Military Medicine.

THE TREATMENT OF GONORRHEA IN THE FIELD.

THEORETICALLY provision for the treatment of cases of acute gonorrhea can be omitted from the preparations for field service. No soldier having an acute venereal distase is allowed to go to the front; no soldier can acquire such a disease at the front; ergo, there will be no such cases to treat at the front. This is all very well in theory, but as a matter of fact—and it is only fact that we are interested in—it will at times become necessary to treat cases of acute gonorrhea in a field ambulance and it is for the best interests of the army that these cases should be handled in the most efficient manner possible. When we consider how long a chronic gonorrhea may drag on, in spite of the most approved methods of treatment, and how this disease may either actually disable a man or give him a good excuse for "slacking," the importance of effective treatment becomes still more obvious.

Lieut. Col. E. T. Burke, of the English army, writing in the *Lancet* for May 9, calls attention to this problem. Dr. Burke was in charge of a field ambulance and on one occasion, when two days at sea with a troop-ship, five cases of acute gonorrhea presented themselves for treatment, all first infections which had presented no symptoms on embarkation. In handling these cases Burke at once discarded as unscientific, inefficient, and dangerous, treatment either by the internal use of drugs such as copaiba, sandalwood oil, methylene blue, etc., or by syringe injections of germicides. Instead he decided on the irrigation method, the solution used being, of course, permanganate.

In the five cases quoted lavage was carried out three times daily, the patients were put on a light diet, with no condiments or alcohol; no drugs were given, but water drinking was encouraged. On the third day the discharge became negligible and irrigation was made twice daily for the next seven days. On the tenth day the destination of the troop ship was reached and these men were sent ashore for microscopical examination of urethral smears. This was negative, and the cases were considered cured, although it was thought best to taper off the treatment rather than cease it abruptly.

Dr. Burke concludes from his experience with these five cases that treatment of acute gonorrhea by the lavage method, even if this must be modified considerably by circumstances, is the most successful, causes the most rapid disappearance of symptoms, and is hence the best for soldiers on active service.

It would seem that these conclusions are well justified. When a case of acute gonorrhea develops in a soldier we have two characteristic things: First, the necessity for getting him back on duty as soon as possible. Second, the fact that there need be no concealment or attempt to have the patient go on with his daily duties as is so often the case in civil life. Hence the patient can be at once withdrawn from duty and all his time devoted to the task of getting well. Thus the cure may be effected in a remarkably short space of time and the patient returned to take his place in the fighting line which the military surgeon strives so hard to keep intact.

CEREBROSPINAL MENINGITIS AND MOBILIZATION.

THE one disease which stands out most prominently in its association with the assemblage and the concentration of troops is cerebrospinal meningitis. It has been the experience in war time that in localities where previously this disease was a rarity and the physician would only very occasionally meet a case and then it would be in the frank and outspoken type, mobilization would be followed by severe epidemics both in the military and in the civilian population; and the physicians would of necessity be ill prepared to meet it. This disease has long been known to have a peculiar connection with troops, hence one of its names, troop disease. The condition of ill preparedness to meet this epidemic obtained in England in the winter of 1914-15 and the following spring. There was not even a manual on the subject to be found which could be used as a guide to the army surgeon to meet the emergency (Horder). In our own mobilization the same mistake of unpreparedness should not be made. The physician must be on the alert to catch the first sign of an epidemic, whether he is a military medical officer or a civilian, and both must be prepared to cooperate with each other. Not all attacks of cerebrospinal meningitis have the classical symptoms associated with the disease. To wait for those symptoms before making the right diagnosis is to invite disaster. The mild type of the disease most nearly simulates the symptoms attributed to influenza. For this reason, during mobilization at least, the relation between influenzal symptoms and meningitis must be as firmly established in the minds of the physician as well as the public as is now established between tonsillar symptoms and diphtheritic infection. Both influenza and cerebrospinal meningitis are most common in the winter and spring seasons. Both of them are closely associated with the nasopharynx. The diplococcus of Weichselbaum can be had in culture from this locality in the active cases, whether of mild or severe type, and in the carrier population. In the active cases, however, it begins to disappear from the nasopharynx in the later stages of the disease. The relation of the carrier to the spread as well as the keeping alive of the disease in a locality has been well established in this disease. It is the most important and the most difficult problem the profession has to meet in solving the question of the spread of the disease. Mild cases or healthy carriers may spread very severe types of the disease.

In order to prevent the spread of epidemic cerebrospinal meningitis among the soldiers or the civilian population it is necessary to examine frequently, by taking cultures from the nasopharynx, all persons suspected of having or of harboring the disease. Carriers and mild types must be immediately isolated and treated. For active treatment nothing holds forth so much hope as serum therapy. Flexner found that if serum treatment was given between the first and the third days the mortality was reduced to 18.1 per cent. If delayed till the seventh day the mortality rose to 36.5 per cent. The general mortality of cerebrospinal meningitis has been reduced through serum treatment from 80 to 30 per cent. In epidemic localities every influenzal

type or other suspicious disease should be regarded as one of meningitis until culture or course decides otherwise. The spread of the disease is by the so-called droplet method where the secretions from the nasopharynx are carried to the sensitive mucous membranes of healthy but susceptible individuals. As a general prophylactic measure, therefore, the public must be educated to the dangers of bad habits with regard to the nasopharynx, and the profession must be careful to prevent the scattering of the secretions from the nasopharynx of infected cases or of suspected ones. In the training camps it would be preferable for this and other reasons to have the troops in huts or tents, if possible, rather than in large barracks.

Rendering Drinking Water Potable.—H. D. Dakin and E. K. Dunham give a description of a new substance for the preparation of stable tablets for the sterilization of polluted water in a report to the Medical Research Committee. After experimentation with several substances they found that the most suitable one is *p*-sulphondichloraminobenzoic acid—$Cl_2N.O_2S.C_6H_4.COOH$. It is easily prepared from cheap, readily available materials, and appears to be effective and reasonably stable. The presence of the COOH group confers a slight but definite degree of solubility in water, which is increased by dispensing it with alkaline salts such as sodium carbonate or bicarbonate, borax or sodium phosphate. Since the synthetic name of the disinfectant is inconveniently long for ordinary use, the experimenters propose to apply the name "halazone" to the tablets containing it. The abbreviated name gives some indication of the character of the compound.

The technique employed for bacterial results was that in general use. Five or ten standard drops of the treated water were generally used for plating on agar for counting the surviving organisms. Suitable controls were invariably carried out. A concentration of 1:300,000 is sufficient to sterilize an ordinarily heavily contaminated water in about thirty minutes. Such a concentration could be relied upon to remove coli, typhoid or cholera organisms. The concentration of disinfectant given above is just perceptible to the taste, especially in warm water containing little organic matter, but the water is perfectly palatable. One point of advantage possessed by this disinfectant over most hypochlorite preparations is the fact that the active chlorine is less rapidly used up so that the process of disinfection continues for a long period.

The starting point in the preparation of the substance is *p*-toluenesulphonamide, a product which is readily obtained by the action of ammonia on *p*-toluenesulphonic chloride. The latter substance is a very cheap waste product in the manufacture of saccharine, and is available in relatively large quantities. The final preparation of *p*-sulphondichloraminobenzoic acid is as follows:

Twenty grams of *p*-sulphonamidobenzoic acid are dissolved in 200 c.c. approximately normal sodium hydroxide (2 mols.), warming if necessary. About 200 grams of crushed ice is then added, and the mixture saturated with a rapid current of chlorine. The reaction is most conveniently carried out in a fairly wide-mouthed flask, which may be shaken while the gas is being introduced. If the temperature should rise more ice can be added. A white, rather chalky precipitate of the dichloramino acid is at once precipitated. The acid is filtered off, using suction, well washed with cold water, and dried *in vacuo* on a porous plate. The dry substance is practically pure, and may be powdered and preserved apparently indefinitely. Prepared by this method, the yield of the dichloramino acid is practically the theoretical amount.

The substance is sparingly soluble in water and in chloroform and insoluble in petroleum. It readily dissolves in glacial acetic acid, crystallizing in stout prisms, which melt at 213° C. The substance explodes feebly when rapidly heated on platinum foil, but, compared with most members of the group, is remarkably stable. The purity of the compound may be checked by titration as follows: 0.1 gram is weighed out, dissolved in glacial acetic acid and potassium iodide added. The liberated iodine is titrated with decinormal sodium thiosulphate, of which 14.8 to 14.9 c.c. will be required.

In the preparation of the tablets Dakin and Dunham have found no very marked differences in the behavior of the sulphondichloraminobenzoic acid when made into tablet with salt and either sodium carbonate or bicarbonate, dry or crystallized borax, or sodium phosphate, although the crystallized salts are undesirable if the tablets are exposed to high temperatures. The sodium carbonate tablets seem as satisfactory as any, and a convenient formula for tablets weighing 100 to 105 mg. is to use sulphondichloraminobenzoic acid 4 per cent., sodium carbonate 4 per cent. (or dried borax 8 per cent.), sodium chloride (pure) 92 per cent. The acid should be ground up with the dry salt and the sodium carbonate added subsequently. The mixture may be passed through a 40 mesh sieve. No lubricant or other addition is necessary and should be avoided. The strength of the tablets should be tested by dissolving in acetic acid and potassium iodide solution, and titrating with sodium thiosulphate as already described (1 c.cm. of N/10 thiosulphate = 0.00675 gram of the dichloramino acid). They must not be allowed to dissolve in water and subsequently titrated, as then decomposition occurs. The tablets should be stored in small amber glass bottles. Tablets so prepared of the weight mentioned contain about 4 mg. of the disinfectant, and are suitable for the sterilization of a liter or quart of reasonably heavily contaminated water. In the case of extreme contamination a second tablet may be necessary. These tablets are more stable than other similar compounds. When kept in amber bottles under ordinary conditions no decomposition was noted in two months; but when exposed to bright sunlight in clear glass tubes decomposition was more marked. On the whole, dry borax or dry sodium carbonate appear preferable to the other salts.

The cost of the finished product is rather difficult to estimate, but the experimenters consider it safe to say that the tablets could be sold at such a price that 100 gallons of water could be sterilized at a cost of one penny (English money).—*British Medical Journal*, May 26, 1917.

Military Orthopedic Hospitals.—W. Colin Mackenzie, writing on this subject, states that orthopedic cases comprise in one form or another a large

proportion of the men invalided from abroad with severe surgical injuries. Military orthopedic cases are held by the Army Council to include the following: (*a*) Derangements and disabilities of joints, simple and grave, including ankylosis. (*b*) Deformities and disabilities of feet, such as hallux rigidus, hallux valgus, hammer toes, metatarsalgia, painful heels, flat and claw feet. (*c*) Malunited and ununited fractures. (*d*) Injuries to ligaments, muscles and tendons. (*e*) Cases requiring tendon transplantation or other treatment for irreparable destruction of nerves. (*f*) Nerve injuries complicated by fractures or stiffness of joint. (*g*) Certain complicated gunshot injuries to joints. (*h*) Cases requiring surgical appliances.

These cases naturally fall into two groups—those whose disablement is only temporary and who after treatment will be fit for military service again, and those who are so disabled that they must inevitably be discharged from the army. The wounded soldier receives immediate treatment in a general military hospital. If his case comes into the category of orthopedics, as defined above, he is then transferred to one of the orthopedic centers for special treatment. If his disablement has been only temporary, he may be sent for aftertreatment to a command depot until ultimate recovery and return to military duty.

The command depot is a convalescent camp equipped with all the necessary apparatus for treatment, but mainly organized and controlled under purely military officers, with the object of hardening men by suitable exercises and graduated for return to active service at the front in a period of about six months. The men live in huts. Beds are wooden forms with straw palliasses and military blankets. Ordinary diets only are given. The huts are heated by stoves.

The cases suitable for admission to a command depot are: Men recovering from gunshot wounds not involving joints or nerves. United nerves giving normal action to muscles. Pott's fracture, Colles's fracture, with no ankylosis of joints. Injuries to left hand not to such a degree as to prevent the use of a rifle. Simple myalgia without obvious organic symptoms.

All scars should be firmly healed and not situated at points of regular pressure of equipment, for example, shoulder, scapula, waist. Spinal injuries when there are resultant symptoms as headache or paresis; shell shock with the slightest tremor or mental impairment; paralyzed limbs, drop foot or hand, and neuritis, are not considered suitable cases for admission. The command depots are visited regularly by an orthopedic surgeon, to help the staff in their choice of cases for orthopedic treatment. The soldier who is permanently disabled and utterly unfit for further military service undergoes similar treatment in the general and orthopedic hospitals, and is finally discharged and pensioned.

In each orthopedic center, besides surgical operations, massage, electrical treatment, hydrotherapy, and gymnastic exercises, a series of curative workshops have been established with successful and valuable results. These curative industries serve a twofold purpose. First—and this is most important—they are directly curative by giving exercise, under medical supervision, to the affected part. They are also indirectly curative through their profound psychological influence upon the patient. Mental and bodily activity are thus encouraged. In the second place, these industries enable a certain number of the men to acquire a trade or craft, and are thus made more valuable to their community by the increase in their wage-earning power after discharge. A certain monetary value of the work done is beneficial to the institution. The curative workshops are an important evolution of the war.

The permanently disabled soldier is not lost sight of after discharge from the hospital and army. He then comes under the care of the Statutory (Pensions) Committee. If possible he goes back to his old trade or employment, or he may find work in a new craft or trade, probably learned in the curative workshop.

The present urgent question is how best to treat the soldier or sailor who through disablement has to be reeducated and thus be restored to social and professional efficiency in varying degrees. The problem, however, is being strenuously attacked and worked out.—*British Medical Journal*, May 26, 1917.

The Leucocytes in Cases of Irritable Heart.—Grace Briscoe, in a report to the Medical Research Committee states that this investigation was undertaken with the object of determining what changes, if any, are present in the white blood cells in cases of "irritable heart." All the patients investigated were admitted to the Mount Vernon Military Hospital suffering from the symptoms associated with the above condition—breathlessness or palpitation on slight exertion, faintness, giddiness, precordial pain, and general lassitude. Preliminary counts had shown that in some cases the number of nongranular cells in the capillary blood was considerably greater than normal, both absolutely and relatively, to the granular cells. Further investigations were undertaken to decide if this change was constant, and if it could be regarded as of value in diagnosis and prognosis.

A list of these patients drawn up by the clinicians in accordance with the severity of the symptoms was compared with a similar list based on the blood findings. The correspondence between the two methods of classification was very close. An analysis of these cases demonstrates that the men who have a history of symptoms dating back many years show a higher lymphocyte count than the men who date their symptoms as subsequent to service abroad.

The cases were divided into two classes: In Class A, in which the onset of symptoms dates back to civilian life, the highest leucocyte counts range between 37 and 57 per cent., the average being 47.5 per cent. In Class B, in which the onset of symptoms is dated from the strain of actual service in the trenches, the lymphocyte counts range between 32.2 to 41.5 per cent., with the average at 38.2 per cent. In the controls the average of the highest lymphocyte counts is 38.2 per cent. This classification seems to indicate that men who have shown signs of "unfitness" in civilian life are very liable to break down while still in training, and are not likely to improve much under treatment, while the men who have passed through their training successfully and then break down under the strain of foreign service are likely to obtain considerable benefit from treatment.

It cannot be said definitely that a normal blood count in these patients excludes a diagnosis of "irritable heart." On the other hand, a blood count which shows a marked deviation from the normal is a positive sign entirely outside the control of the patient, and may be regarded as a definite objective point in diagnosis. The blood count does not give much help in prognosis, as the condition of the blood appears to vary with the general condition, and this can be judged by the usual clinical methods.

The following conclusions apply to patients who show the signs and symptoms referred to at present under the term "irritable heart." At absolute rest there is a slight leucocytosis or no leucocytosis. While up and about there is a decided leucocytosis. In many, and especially in cases of long standing, there may be a relative and absolute lymphocytosis. The variability of the different kinds of leucocytes is greater (more than double) than in normal individuals. The response to muscular exercise is similar to that found in healthy subjects, but is exaggerated in its degree. This exaggerated response can be used as an objective sign in diagnosis. The degree of leucocytosis and of variability in percentages after exercise is proportionate to the severity of the symptoms.—*British Medical Journal*, June 2, 1917.

Treatment of Wounds in the Casualty Clearing Station.—It is the object of every casualty clearing station to treat and retain all patients until they can be safely sent down by ambulance train. According to Cuthbert Wallace, in times of comparative peace and quiet there is no difficulty in carrying this out, and consequently whatever standard of treatment is required from the surgical standpoint can ordinarily be obtained. However, in times of heavy fighting, especially when there is the certainty that many more wounded will arrive during periods extending over days and weeks, the provision of empty beds necessitates sending patients away who might, with advantage, be retained a little longer. This pressure does not prevent the performance of all really necessary operations, and these are now always performed. If the requirements of the English army did not place a limit on the number of nurses, surgeons, orderlies, and patients who can be retained in close proximity to the fighting line, there would be no reason why all patients should not be kept near the front. There is this limit, however, in every war, and casualty stations are maintained everywhere in as great numbers as the military authorities can permit. For more than two years it has been the policy of the British Army Medical Service to make the casualty station the chief place for the treatment by operation of the dangerously wounded man who requires prompt treatment, rather than the field ambulances. The latter is too mobile and too frequently moved a unit to be thoroughly equipped surgically and it is better to move a patient before operation than directly after he has been operated on.—*British Medical Journal.*

Disprove the German Scare Propaganda.—The Equitable Life Assurance Society for the Pittsburgh district has been able to discredit some silly tales, inspired and financed by Germany, to discourage American physicians and nurses who may think of enlisting for war service. It has been said that the average life of a physician or a Red Cross nurse at the front is only a certain number of days. Persistent reports of maimed and outraged women at the hospitals have been sent out by the same pernicious German propaganda, which further asserts, parenthetically, that Germany has 850,000 youths coming to military age each year. All of these statements have been disproved. The above named insurance company—and insurance companies do not guess at figures—states that Germany has less than 400,000 youths coming to military age annually. Instead of 65,000 physicians dead in France, 150 is nearer the mark on all the battle fronts. Our nurses, they assert, are as safe as in our own hospitals.

To Combat Venereal Disease.—The Department of the Army has organized a section which will devote its attention exclusively to the venereal disease problem, in cooperation with the United States Public Health Service and the sanitary and training camp divisions of the Army Medical Department. Maj. F. F. Russell, M. C., U. S. A., will have charge of the laboratory investigations. Maj. William Allen Pusey, M. R. C., of Chicago, will devote himself to the scientific side of the problem. Educational and sociological studies into environmental conditions will be made by Maj. William F. Snow, M. R. C.

Psychiatrists and Neurologists Needed to Examine Troops.—The recent decision of the War Department to examine the National Guard troops in their armories before sending them to camp, makes it necessary to secure at once a large number of examining physicians. To meet the situation the Surgeon General of the Army has arranged to accept the work of qualified physicians on contract. Psychiatrists and neurologists may contract for specified duty, at a specified place, for a specified time, or for part time. This latter provision makes it possible for many physicians who cannot enlist, or who cannot give all of their time to the work, to give part time. Further information can be obtained from Dr. Frank E. Williams, 50 Union Square, New York.

Auxiliary Medical Corps for Emergencies.—Three hundred surgeons of New York have been enrolled in the Police Surgeon Auxiliary Medical Corps, which includes the surgeons of the Police and Fire Departments. The members of this corps will be organized into units to handle surgical cases in any emergency that may arise within the city. The Women's War Auxiliary of the New York Hospital raised $1,500, and it was through their efforts that this body was organized. Dr. Edward T. Higgins, as chief police surgeon, is the commanding officer. The borough chiefs are Dr. Harold Barclay, Manhattan; Dr. Alvin E. Munson, the Bronx; Dr. Walter A. Sherwood, Brooklyn; Dr. William A. Scoville, Queens; and Dr. Alfred H. Thomas, Richmond.

Camp to Become Hospital.—Madison Barracks at Sacket Harbor, which is to be closed as a reserve camp on August 15, will be converted into a military hospital, according to advices from the Government.

The X-Ray Examination of Guardsmen.—The *x*-ray is now being used in the examination of the National Guardsmen. It is stated that of the first 95 men subjected to this test 12, or 12.6 per cent.,

showed existence of thoracic disease. All of these men had done service on the Mexican border. The State Department of Health says the *x*-ray enables the examiners to pick out the men who would be in danger by acceptance for foreign service.

Trachoma in Recruits.—The Public Health Service has issued a warning against the acceptance of victims of trachoma for the Army. An applicant who is suffering from well-marked trachoma should not be immediately rejected, but should be given treatment and his trachoma cured. He can then be reexamined to determine whether he has resulting visual defects sufficient to cause his rejection.

Hospitals at the Army Cantonments.—Plans for hospitals at all of the sixteen Army cantonments have been completed by the office of the Surgeon General, and work on them will be commenced and rushed to completion before the troops are assembled under the selective service law. The hospitals will have, with few variations, 34 wards, including two isolation wards. Separate barracks are to be provided for hospital internes and other employees, and special buildings for other hospital needs.

Elks to Build War Hospitals.—The War Relief Commission of the Benevolent and Protective Order of Elks has plans for the collection of a million-dollar fund for the erection of base hospitals in France, for aiding the families of soldiers, and for the reeducation of disabled men to fit them to fill some useful station in life. The hospitals will be under the supervision of the Red Cross, but will be named, numbered, and designated as hospitals provided by the Elks.

Two More Red Cross Missions.—It is announced that a third Red Cross Commission is to be sent to Europe to study conditions and distribute relief in Roumania. A Red Cross unit of twelve doctors and twelve nurses accompanies the commission, which is composed as follows: Dr. Francis W. Peabody of Boston, Dr. Gideon H. Wells of Chicago, Dr. Roger Griswold Perkins of Cleveland, Dr. Robert J. Bryan of Richmond, and Bernhard Flexner, a lawyer of Chicago, and Arthur Graham Glasgow, an engineer of Washington, D. C. The following physicians will be members of the Red Cross unit: Dr. W. D. Kirkpatrick, Bellingham, Wash.; Dr. Richard Penn Smith, Fort Loudon, Pa.; Dr. D. J. McCarthy, Davenport, Iowa; Dr. George Y. Massenberg, Macon, Ga.; Dr. R. H. Rulison, Syracuse, N. Y.; Dr. B. C. Hamilton, Syracuse, N. Y.; Dr. Benjamin Earl LeMaster, Macomb, Ill.; Dr. Louis H. Limauro, Lynn, Mass.; Dr. E. F. Hird, Bound Brook, N. J.; Dr. W. T. Lowe, Pine Bluff, Ark.; Dr. Joseph P. H. Gruener, Chicago; Dr. Geo. Duro Guca, Chicago; Dr. William J. Kucera, New Prague.

A fourth commission, headed by George F. Baker, Jr., vice-president of the First National Bank of New York, is to be sent to Italy. The purpose of this commission is to advise how American Red Cross activity can best be exerted to meet the needs of the soldiers and the civilian population of Italy. The commission includes John R. Morron, president of the Atlas Portland Cement Company; Dr. T. W. Huntington of California, president of the American Surgical Association; Dr. Victor G. Heiser of the U. S. Public Health Service, and Nicholas F. Brady of the Central Trust Company, New York. Chandler R. Post, professor of Greek and fine arts at Harvard, and a noted authority on Italy, accompanies the commission.

Furloughs for Drafted Medical Students.—In order to forestall any serious effects to home hospitals because of the unusual call for physicians in the army and navy, the Government has provided a furlough for drafted medical students which will continue so long as they keep seriously at work. The United States Army will not accept a man for its Medical Corps until he has had a year in a hospital as interne. As the internes are considered students until they have completed their year, it is likely that the furlough will be extended to them. With the cooperation of the Medical Department of the Army a balance will be struck between home and overseas service. Not all of the more experienced men will be called for the Army. A few of the older men of the profession will go, and with them those who have completed their first year as internes.

Two More Base Hospitals in France.—The Johns Hopkins and Roosevelt Hospital units, organized under the direction of the Red Cross, have arrived in the American Army zone in France and are established some twenty miles apart. Each of these organizations is capable of caring for from 1,000 to 1,500 patients.

A Fleet of Hospital and Ambulance Ships Projected.—The Ward liner *Havana*, a 6,391-ton vessel, is to be transformed into a navy hospital ship, and will be the first of a fleet of three similar vessels and a number of smaller ambulance ships to be added to the expanded naval establishment. When the new vessels are available, the *Solace*, now the Navy's only hospital ship, will be transferred to the group of ambulance ships.

Minor Defects in Drafted Men.—The medical examiners of drafted men in this city announce that arrangements have been made with Bellevue Hospital by which men who want to enter the draft army, but are barred by physical disability that may be removed by operation, are to be treated free. It is hoped that other hospitals will make similar offers.

Personals.—Dr. Alanson Weeks of San Francisco has been appointed chief surgeon of Army Base Hospital No. 30.

Dr. Michael J. Thornton of New York City has been appointed Captain and Assistant Surgeon in the Medical Corps of the United States Army. He is to report to Governor's Island at once.

Dr. William Edward Fitch, First Lieutenant M. R. C., stationed at Plum Island, has been promoted to a captaincy.

Capt. Le Compte du Nouy and Major Lowey, the French field surgeons who have been working with Dr. Alexis Carrel, have arrived in this country to assist Dr. Carrel in teaching American surgeons the newest method of treating trench wounds.

New Army Number Plan.—A modification of the plan for designating regiments of the war armies by number and branch of service only is to be modified so that it will be possible to determine from the number itself whether the regiment is a part of the regular army, the National Guard, or the national army. Any regimental number under 100 will indicate regulars, any number between 100 and 300 National Guard, and any number over 300 national army.

SAVE THE MOTHERS!

IN the United States, and particularly in the rural districts, there has arisen an acute knowledge of the vital need of improvement in prenatal and aftercare of the women who assume the responsibility of childbirth. How are the mothers of the nation to be encouraged in their God-given specialty when in some sections of the country more attention is paid to the swine when they deliver their young, and when in so many instances a woman is expected to fulfill the most sacred function of her life without adequate assistance? Is this neglect because it is taken for granted that the Biblical anathema, "In sorrow thou shalt bring forth children," must of necessity be fulfilled? Or is it because this important function is not computed in money value, not bringing in financial returns?

According to a circular issued by the Children's Bureau of the U. S. Department of Labor, there are annually about 15,000 deaths from maternal causes in the United States, and available statistics show no decrease in maternal mortality since 1900. These 15,000 deaths are but a rough indication of preventable illness and suffering among mothers. The statement is made that more women from fifteen to forty-five years of age die from conditions associated with childbirth than from any other disease except tuberculosis. Little has yet been done to show women of child-bearing age that much of this waste of life and health is unnecessary. Even less has been undertaken by communities to provide protection for them, and while many communities have instituted costly measures for the reduction of their typhoid and tuberculosis death rates, practically nothing has been accomplished to lower the death rate among mothers. Since 1900 the typhoid death rate for the country as a whole has been cut in half, and the rate from tuberculosis has been markedly reduced. On the other hand, the death rate from maternal causes has shown no demonstrable decrease.

This suggests that a more general use of existing provisions for scientific maternity care and the extension of provision for such care in all communities, should serve to reduce the number of maternal deaths. Just how the importance of maternity care is to be made plain to a community, and just how skilled care and instruction are to be available for all mothers, are questions to be studied and practically worked out by every community. Even in cities where prenatal clinics and prenatal nursing have been established and good hospitals are numerous, the number of mothers reached is small in comparison with the number who bear their children without proper care. Thousands of mothers all over the country do not have the essentials of safety, chiefly because women have not been taught that the dangers of childbirth are largely avoidable. Under present conditions, many women, even when aware of the danger, are unable to obtain the necessary care; but when all women and all men understand its importance, and demand this care for every mother, physicians will be found to furnish it, medical colleges will provide more thorough obstetrical training, and communities will see to it that mothers are properly protected.

A feature emphasized by Dr. Grace L. Meigs of the Children's Bureau, in an article on "Rural Obstetrics," read before the American Association for Study and Prevention of Infant Mortality, October 16, 1916, is the condition prevalent in rural districts where the inaccessibility of a physician is often added to the other elements of the problem. The bureau has made an attempt, by correspondence with women in various sections of the country, to find out the attitude of the women themselves toward this question of preventable death in childbed. The answers received contain suggestions regarding the great need of more rural nurses and better roads for allowing quicker transportation both of the mother for prenatal examinations by her doctor and of the physician at the time of labor. The whole subject is made perplexing because of the two apparently contradictory facts—that childbirth, to a normal and sturdy multipara, is really a simple performance, and that a complicated case of labor is a grave surgical condition requiring immediate aid. It is difficult to convince a husband or wife whose experience has never included a severely complicated case that all women really need skilled care and rest through this period.

Dr. Meigs offers a partial solution for the situation by the provision, first, of means for the recognition and hospital care of complicated cases of pregnancy and confinement; and second, of a feasible plan whereby normal cases may receive adequate care in their homes. In general, the unit in any plan could be made the county, where centers of maternal and infant welfare could be established. Here mothers could obtain information as to the proper care of themselves and their babies. This would include a county nursing service, a cottage maternity hospital or beds in a general hospital for complicated cases, or for women who would or could be confined away from home; provision for skilled attendance in all types of maternity cases in the home, and provision for obtaining help for mothers, whether confined at home or in hospital.

THE DEVELOPMENT OF SARCOMA AT THE SITE OF OLD FRACTURES.

It has long been taught that when sarcoma affects certain bones, especially the long bones and the lower jaw, spontaneous fracture through the affected portion of the bone is not infrequent; but that sarcoma very rarely develops at the site of an antecedent fracture through healthy bone. This has always seemed somewhat remarkable since many cases have been reported where sarcoma has followed moderate degrees of traumatism, such as simple contusions of the arm or leg; yet the rarity of sarcoma occurring at the site of ordinary fractures is still emphasized in the latest textbooks.

A few quotations from recent standard textbooks will serve to illustrate this point. In the last edition of Rose and Carless' "Surgery," the matter is dismissed in these few words: "In conclusion, one must allude to the fact that a sarcoma sometimes develops at the site of fracture within a comparatively short time of the accident." In Kellogg Speed's new textbook on fractures and dislocations we find the following: "Whether sarcoma follows the trauma of fracture or not is a disputed point. I have removed the mandible for sarcoma of the jaw in a case which gave a history of fracture a year before at the same site, and the size of the tumor and lack of metastases did not seem to indicate that the tumor had been in existence before the fracture. Coley has reported a case, and Griffin reported sarcoma following the plating of a femur for fracture."

In the latest revision of his textbook on "Fractures and Dislocations," Stimson says: "The development of a tumor, sarcoma, at the site of a healed fracture within a few weeks, or after an interval of several years, has been occasionally observed, and apparently belongs in the same etiological group as that of sarcomata following other injuries of bone or soft tissues." Murphy took a still more radical view; for in the "Clinics," June, 1914, he said: "One practically never sees a sarcoma develop at the site of a fracture. One often sees fractures occur at the site of sarcoma, but never the reverse."

In view of these statements, the experience of Bissell (*International Journal of Surgery*, June, 1917), who, in a period of approximately one year, saw six cases in which sarcoma developed at the site of fracture, seems most remarkable. The ages of the six patients were respectively 19, 20, 20, 26, 27, and 50; and the respective antecedent fractures in these patients were: Incomplete fracture of the shaft of the left femur, fracture of the shaft of the left femur, transverse fracture at the head of the right humerus, fracture of lower jaw, fracture of the bases of the coracoid and acromion processes of the left scapula, and intratrochanteric fracture of the right femur.

Although it is quite true that these six cases occurred in the course of service at two large hospitals (Bellevue and St. Vincent's), at which the number of traumatic cases seen in the course of a year is exceptionally large, still one must wonder whether or not the development of sarcoma at the site of fracture is as rare as has been believed. Possibly its supposed rarity is at least partially due to neglect on the part of surgeons and general practitioners to report such cases. If this latter hypothesis be true, it is to be hoped that brief reports of all such cases will be published hereafter, in order that we may obtain more accurate information as to the incidence of this condition.

PUBLIC HEALTH OF ENGLAND DURING THE WAR.

The effect which our participation in the war will have upon the health of the country at large is a matter of the utmost importance to all Americans, especially to members of our profession. It is interesting not only from an academic standpoint, but also from a pragmatic one. When we consider that many thousands of physicians will be withdrawn from practice for military purposes, and that those remaining will have their duties vastly increased, perhaps even doubled, it can readily be understood that the general health of the nation becomes a matter of the utmost concern to the profession. History offers us no precedent by which to theorize, but fortunately, in this regard at least, we have the experience of our Allies to guide us. Naturally we turn to England as being the nation most like us in ethnological factors, customs, climate, etc. There has just appeared the report of the Registrar-General of England, Sir Bernard Mallet, for 1915. To be sure, this covers a period a year and a half distant, but it was a period when the war was already well under way, and in any event its figures are the most recent official ones available.

Coming to study them, we find many interesting facts. The marriage rate was the highest on record, 19.5 per 1,000, and the birth rate the lowest, 22 per 1,000. This birth rate, however, compares favorably with those of the other belligerent countries. The civilian death rate was 15.7 per 1,000, 1.2 above the average in recent years for the whole population, but below the rate for any year preceding 1903. In evaluating these figures, however, we must remember that the war has meant the withdrawal of an immense number of men in good health; naturally, we would expect the death rate to be somewhat higher in those left.

A number of statistics are given bearing on child welfare. About 16 per cent. of all deaths were of infants under one year, corresponding to a mortality of 110 per 1,000 births. The immediate chances of survival differ but little at birth in the town, as compared with the country, but the pernicious influences of town life speedily appear and make themselves felt increasingly during the first year of life and to a still greater extent in the second and

third years, when the city mortality is about twice that of the country. The mortality of illegitimate infants was about twice as high as that of legitimate ones; particularly the deaths attributed to syphilis were given as eight times as numerous, perhaps on account of the greater frankness in stating this cause in dealing with the nameless babies.

Taking up a few of the most prevalent diseases causing death, it is found that the death rate from typhoid fever was the lowest on record, but influenza was more fatal than any year since 1900; measles also showed a high destructive power. Diphtheria gave the same figures as for 1914, that is unusually heavy ones, owing to many epidemics. Scarlet fever showed a decrease. Pulmonary tuberculosis showed a marked increase; here again the withdrawal of the sound males must be considered. Cancer showed an increase. Taking all in all, the Registrar General's report is about what would be expected. Practically all diseases showed an increase in the death rate, probably for the reason given above. The decrease in typhoid mortality can doubtless be accounted for by the increase in the frequency of vaccination for this disease, this in turn being partly due to public education and partly to military vaccination being emulated by the civilian population.

RATIONAL ORGANOTHERAPY.

Owing to the concatenation and mutual interdependence of the glands of internal secretion it becomes increasingly difficult to prescribe rationally for disease depending on diseases or disorders of these bodies and a sort of polypharmacy is for many the only index to treatment in the hope that the organism will appropriate just what it chiefly needs. This plan might answer if organotherapy was limited to deficiency diseases, but several of its products have an independent physiological action and must therefore be left out of any mere feeding proposition. Again the status of the sexual glands is dubious, for we hastily assume that one sex cannot possibly benefit from the genital products of the other, although it is physiological for the female to absorb the testicular secretion of the male and the male fetus and the male nursling must partake of the internal secretions of the mother.

Houssay in the *Revista de la Asociación Médica Argentina* for April makes a praiseworthy attempt at a rational organotherapy in seeking to isolate certain groups of activities and indications. Simplest of all is the substitutive or supplementary theory. Whenever as a result of disease, injury, or operative removal of an organ deficiency symptoms develop, the subject should receive the product of the corresponding organ of some animal. Ovarian substance is the chief representative of this class. The conditions differ when thyroid substance is used in congenital myxedema, acquired myxedema, operative thyreopriva, etc. Thyroid substance is more than a mere food, for it has a pronounced independent physiological action on these subjects which is either of no benefit or harmful for other subjects. The author terms this action homostimulant and homoregulating; but has to admit that in certain affections in women ovarian extract shares in this property with thyroid substance (even if devoid of a true physiological action). For example, the action of ovarian extract on the menses is something more than substitution. When thyroid substance shows its ability to influence favorably the function of the hypophysis or ovary such activity is termed by the author heterostimulant. Conversely the product of one gland may inhibit the overaction of another gland, a doubtful example being the power of mammary gland substance to check overaction in the ovaries when such overaction is held responsible for the development of uterine fibroids. This the author terms the inhibitory action. He does not go very far into the province of these two activities (heterostimulant and inhibitory) because they lead into deep water, and it is unprofitable to speculate on the interrelations of more than two glands at a time. Last of all is symptomatic organotherapy, which deals with physiological action of adrenalin and pituitrin. These substances are nothing more or less than drugs, although under certain conditions they can doubtless fill any of the rôles of organ extracts already mentioned. Their substitutive and homostimulant action, however, seems somewhat vague and inconstant. Adrenalin is of very limited value in Addison's disease, and this is true of pituitrin in destruction of the hypophysis, although in mere hypofunction these substances must necessarily be useful.

FRUITARIANISM.

In the equatorial region fruits may form the chief source of nourishment, the most extensively used as staples including the banana, fig, date, etc. In the subtropical regions fruits abound side by side with other food classes, and here the hygienist must discriminate as to the amount of fruit advisable in a mixed diet. In the temperate zones excessive consumption of fruits, when fresh, as a staple of diet is impracticable for several reasons, but they are used extensively in desiccated form, in preserves, etc.

The late Dr. Luis M. Cowley of Havana wrote an article on fruitarianism (*Revista Medica Cubana*, June) not long before his death. "Fruit cures"—for example, the grape cure—go back to antiquity. This use of fruit, however, is not dietetic in the ordinary sense. Whosoever eats fruit as a preponderant article of diet soon learns that it has manifold disadvantages, especially in childhood. Because of the exquisite flavor and refreshing quality of fruit the child is naturally attracted to it and will eat it in excess. The bowel disorders which are apt to follow its use can of course be explained in part by infected dirt and dust (food intoxication from unripe fruit, cherries, etc., has apparently

been traced in some cases to the *B. prodigiousus* on the surface). Much must depend on the evolution of the fruit—whether extremes of heat, cold, humidity, etc., have interfered with normal maturity. Certain kinds of fruit, as oranges, grapes, and ripe bananas, are so bland that they can be eaten freely. Others are laxative, some are astringent, while a few, like the strawberry, have for many persons some specially irritating, if not toxic property.

With some dietetic authorities nuts are classed as fruits, but the fat content of the former should make of them a radically different food class. Fresh fruits are not necessarily eaten raw, for some are improved by cooking. Where fruit is a staple it is usually eaten both raw and cooked, which helps to vary the monotony of the diet.

Only a brief study of fruitarianism is needed to convince one that fruits as a dietetic article may be greatly abused. In hot countries fruit after lying on the ground readily distributes animal parasites, and in our Southern States such fruit has aided in spreading hookworm disease. Insects also deposit their ova upon fruit so that the latter may become a source of peril. In such cases it is the sugar in the ripe fruit which first attracts the insects. This problem differs from that in the Northern regions when certain insects attack green fruit and interfere with its development (windfall apples, cherries, etc.). In the latter case myiasis never results, but various kinds of parasitism can follow the ingestion of fruit which is covered with larvæ. The scolices of the echinococcus have often been found on pears, while the creeping fruits have been plausibly accused of transmitting typhoid fever, dysentery and cholera, as a result of exposure to human dejections. The problem of the danger of dirty fruit in city stalls has been dealt with to some extent by legislation, and screening from flies is obligatory in some cities. In refined households fruit is not only washed well, but often peeled before being eaten.

Fruit is recommended especially for the rheumatic, gouty, arteriosclerotic (preliminary period), and numerous other classes of invalids, for its content of organic acids. Curiously enough, it appears to have value in chronic diarrhea and even irritable stomach, although it would seem to be contraindicated. The apparent value of fruit in constipation is known to the public. Where there is danger of deficiency disease, as in the case of bottle fed infants, sailors, etc., the value of fruit juices is also well known. Hence certain classes of subjects profit by being fruitarians to a considerable extent, but exclusive fruitarianism is a chimera for many reasons. Exotic fruits are always expensive—even the banana delivered in the Northern States is not always cheap when reckoned by calory cost.

Beriberi in Brazil.

The Brazilian literature on this subject is extensive, especially productions of medical men in Bahia. From 1877 to 1885 many graduation theses were devoted to this affection, although since that period but few have appeared. Some of these theses are really valuable productions. In 1916 Dr. de Almeida wrote a monograph on the subject, reviewed in the *Brazil-Medico* for April 21, in which all the Portuguese literature of Brazil is digested. While very prevalent in North Brazil, in the lower Amazon Valley, the disease also occurs in Rio and Sao Paulo. In the first named region it occurs in epidemic incidence, the term epidemic being used advisedly and not as equivalent to endemic. The great falling off in the literature of the disease in Northeastern Brazil, already signified, has no bearing on the frequency or infrequency of the malady, as there are material factors which militate against the publication of medical periodicals and transactions. The States in this portion of Brazil are making very slow progress, the climate is notoriously unhealthy, and general business is much below normal. The amount of beriberi in the army and navy should give some idea of the actual prevalence of the disease. Here, however, it is often confused with paludism, ancylostomiasis, ordinary worm disease, etc., to such an extent that doubt has been expressed as to the existence of beriberi in the service. As is known, however, we have in quinine and thymol, two drugs which should be able to disclose the existence of beriberi by curing the other maladies. Surely it is not seriously claimed that the plasmodium, hookworm, etc., can set up true beriberi; although the quasi epidemic diffusion of the latter might suggest a parasitic cause. It is an open question whether these ailments predispose to the disease. Not much is said of diet, but if beriberi can be due to a regimen of polished rice it should readily appear under similar unbalanced and defective elimination. Clinically the affection is a polyneuritis of a characteristic type. In the apparent absence of a definite food causation Brazilian beriberi appears to be beyond the domain of a simple direct treatment.

The Food Value of Milk.

Although views with regard to the food value of milk are fairly definite, that is, the majority of medical men are agreed as to its great importance, there still are those who believe that the use of milk has not been an unmixed blessing. Dr. Harry Campbell, writing in the *Lancet* of April 1, 1916, offers the opinion that the child, as distinguished from the babe, does not need milk and would not suffer greatly if wholly deprived of it. He points out that milk, affording as it does a peculiarly favorable soil for the growth of germs, has carried disease and death to thousands of children. He argues that it is only since man first domesticated the cow and goat, and this from the point of view of his evolution was but as yesterday, he has been supplied with any milk other than human, and it is absurd to suppose that before that time his health suffered from the lack of cow's or goat's milk. Even to this day many peoples are without any. Campbell does not make the point that dairy milk is a useless food for man, but merely that it is not essential to him after the nursing period. Its chief value to the human race, he says, is as a source of butter and cheese, two highly concentrated and agreeable foods, admit-

ting of prolonged storage. He, therefore, thinks that it would be wise during the period of war, at least, to reduce the consumption of milk to a minimum, and to make as much butter and cheese as possible, especially the latter, on account of the large amount of protein it contains.

Remarkable Unanimity of Expression by Reviewers.

The book on cancer by Dr. Bulkley, which appeared a few months ago, has received considerable notice from reviewers, not always, as may be readily understood, favorable. Surgeons and pathologists do not as a rule regard with approval the medical theory of cancer which looks upon the condition as a general disease of metabolism with local neoplastic expression. But there is a paragraph in the book, in which the action of the New York City Commissioner of Health in urging the detestable practice of biopsy is condemned, that has received the enthusiastic and unanimous approval of the reviewers. In the latest notice brought to our attention, published in *Medicine and Surgery* for July, the reviewer, after some rather unfavorable general comments, says: "However, there is one statement in the book with which the reviewer can agree —namely, that the New York Board of Health is doing a very dangerous thing in offering to diagnose biopsy material from a suspected malignant." Some day perhaps, after Congress has passed the prohibition amendment to the constitution, after strap-hangers in the street-cars are given seats, and after all the restaurant cooks have had a bath, whoever is responsible for this fearful blunder may find time to question those who know something of the subject and learn that by his ignorant obstinacy, if he has persuaded others equally ignorant to follow his urging, many innocent women have been condemned to the horror and misery of death from cancer.

News of the Week.

Quarantine Station in the Philippine Islands.—President Wilson has signed an executive order setting aside and reserving the Island of Cauit, Province of Cebu, Philippine Islands, for the use of the Quarantine and the Marine Hospital Services. This island is now being used by the United States as a quarantine station.

Medical Care of Injured Federal Employees.—A Public Health Report of July 20 calls attention to an Act of Congress which provides for the medical care of injured Federal employees. This act is known as the "United States Employees' Compensation Commission" and creates a commission to see that the provisions of the act are carried out. In accordance with these provisions, civil employees of the United States who are injured while in the performance of their duties shall be furnished, upon application and without personal charge, reasonable medical and surgical treatment by all medical officers at first, second, and third class relief stations of the service, in accordance with certain prescribed rules set forth in the act.

Drink As a Cause of Homicide.—According to the State Department of Health, 24 per cent. of all the homicides in the State of New York, outside of the City of New York, were owing to the use of alcohol. This statement is based on information furnished by the coroners throughout the State. During the year 1916 there were 128 cases of homicide in the State, outside of the City of New York; in 36 of these liquor was said to be the cause of the crime. The Secretary of State also informed the department that 96 per cent. of all the revocations of automobile licenses were on account of intoxication.

Impure Food Condemned.—According to reports filed with the Department of Health of New York City, 219,963 pounds of foodstuffs have been condemned within the last week by the Bureau of Pure Foods and Drugs. It is said that the retail value of this food was $30,000.

Dr. George D. Stewart of New York City is at the Mayo Brothers' Sanatorium, Rochester, Minn., where he was operated on for goiter on May 24. The operation is reported as having been successful.

Dr. Saxton Pope of San Francisco has been appointed surgeon in chief of the San Francisco Emergency Hospital service to succeed Dr. Alanson Weeks, resigned.

Dr. Raimundo Menocal, a noted surgeon of Havana and Secretary of Sanitation in the Cuban Government, died on Tuesday of this week of disease of the heart.

Site for Country Tubereulosis Hospital.—Monmouth County, N. J., has purchased a farm of 138 acres near Freeport for $7,500, which is to be used as a site for a tuberculosis hospital.

Submission to the Health Department Required.—At a recent meeting of the Board of Health of New York City the following new section of the Sanitary Code was adopted, to take effect immediately: "No public dispensary where communicable diseases are treated or diagnosed shall be conducted or maintained otherwise than in accordance with the regulations of the Board of Health." Under this section the Department of Health expects to compel dispensaries either to give up their departments for the treatment of venereal diseases or to submit to control by the Department of Health.

Annual Report of Mount Sinai Hospital.—This report, which has just been issued, shows that the expenses of this institution last year were $533,057, or $47,489 in excess of receipts. There were 8,832 patients admitted to the hospital, 6,120 of whom received free treatment. The report contains the detailed account of the expedition to Mexico for the study of typhus fever under Drs. Peter K. Olitsky, Bernard S. Denzer, and Carlos E. Husk.

Labor Sanitation Conference of Greater New York.—This is the name of a new organization which has its headquarters at 32 Union Square East. It comprises many labor unions and is to maintain an intimate relationship with the Department of Health. Its purpose is to provide ways and means for labor to express its sanitary needs, and to establish direct official communication with official sanitary agencies.

Obituary Notes.—Dr. Edward George Rave, a graduate of New York University, in 1876, died at his home near Hicksville, L. I., July 23, aged 74 years. He was for thirty-five years chief physician of the Long Island Railroad, and at one time

vice-president of the College of Pharmacy of Brooklyn.

Dr. SARAH A. FRENCH BATTEY, who retired from active practice seven years ago, died at her home in New York City, at the age of 56 years. She was a graduate of the Women's Medical College of New York City, in 1889, and formerly a member of the New York Academy of Medicine and the Medical Society of the County of New York.

Dr. EDWARD BARNWELL BANGASSER and Dr. SIGMUND INDA, both graduates of the Buffalo Medical College, in 1913, and both of Buffalo, were accidentally killed in an automobile accident near Buffalo, on July 18.

Dr. GEORGE E. BUSHNELL died after a lingering illness at his home in Rochelle, Ill., on July 10, at the age of 62 years. He was a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1885.

Dr. JOHN C. MURPHY, who practised medicine in Hinesburgh and later in Richmond, Vt., died in the hospital at Fort Ethan Allen on July 19, of purpura hemorrhagica. Dr. Murphy was born in 1882, was graduated from the University of Vermont Medical College, in 1905, and was recently called to the United States service, receiving an appointment in the 18th Cavalry.

Correspondence.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

FOURTH OF JULY IN PARIS—CONSOLIDATION OF ARMY AND RELIEF WORK—PAUCHET'S ANESTHESIA—A TRIO OF NICKNAMES.

PARIS, July 10, 1917.

I PRESUME this is the first time in history that Paris has celebrated the American Independence Day. But the occasion was an unusual one and might well have been made a day of rejoicing, even had it been any other than the Fourth of July; because for the first time, American soldiers fully equipped for warfare, paraded her streets to fight by her side in the cause that has become that of the whole world against the German pretentions.

Never were there such crowds as filled the streets from the barracks where our soldiers were housed to Picpus Cemetery, where by the side of the tomb of Lafayette were spoken the words that pledged "our fortunes, our lives, our sacred honor" to that great day of victory, when the Hun shall be compelled to accept the terms of peace proffered him by his conquerors.

Our boys, four abreast, hundreds strong, with swinging stride marched between two solid masses of seething, shouting humanity, the whole length of the route of about three miles. Their hats, belts, guns, pockets sprouting with the flowers showered upon them at every step, with laughing girls and women clinging to the arms of those forming the outer row. The whole city is decked with the Stars and Stripes, and great was the flow of oratory in many places, including the Sorbonne.

The Government had printed leaflets giving a résumé of American history, and statistical information, and her reasons for joining in this war, which were read and distributed in all the schools of France.

The boys left their barracks last evening for the rendezvous at the front, where our forces are to concentrate.

Colonel Bradley, head of the Army Medical Corps, with all his force of aids, is busy at headquarters, examining applicants for medical service; Colonel Murphy is consolidating the different units of relief established in and about Paris into his new Red Cross organization, and a host of men are trying to get out from under and into the army medical service.

There was a great deal of duplication and expenditure of unproductive effort in the American organizations in Paris; and the work being accomplished by Colonel Murphy in their consolidation will not only save an enormous sum of money, but will result in more good being accomplished.

I learn from those in authority that definite plans have been adopted to educate the men on the aspects of the social evil in France, and certain rigid regulations are in force to control the men and protect them as far as possible by prophylaxis. In case one is taken by venereal disease and cannct show by his card that he has appeared for preventive treatment, his first punishment is loss of a month's pay, and this may be followed by court martial. The blow struck at their pocketbooks, I imagine, is the one that will be universally effective.

I recently had the pleasure of meeting Sir Arbuthnot Lane of London, and Sir Berkeley Moynihan of Leeds, two of England's most celebrated surgeons, who came in Paris to study the system of regional anesthesia, practised by Professor Pauchet, who sent for me to meet them at his clinic, to make certain of some one who could speak English.

The visitors were much impressed by the effectiveness of the anesthesia, as well as by the dexterity and ease with which Pauchet operated in five stomach cases in less than two hours, controlled wholly by this form of anesthesia, and expressed the opinion that its employment ought to be brought into general use.

It is a fact that this improved form of anesthesia has gained many adherents and is coming very generally into use among the army surgeons. There are none of the major or most delicate of the minor operations which may not be performed under it, and it possesses many advantages over general narcosis, especially in cases where it is important to conserve all the vital forces of the patient.

The French soldiers are called "poilus"; the English are "Tommies"; and upon the arrival of the American troops quite a competition grew up between the names of "Teddies" and "Sammies" by which to designate them; and the Teddies were rapidly gaining the ascendancy when General Pershing settled the matter by stating to the newspaper correspondents, who regularly call upon him, that, as the wards of Uncle Sam, the appropriate name for our soldiers would be "Sammies."

146, AVENUE DES CHAMPS ELYSÉES.

Sporotrichosis in a Tuberculous Subject.—Bizard and Blum relate the case of a subject with visceral and articular tuberculosis who developed what was to all intent a tuberculous lesion over the wrist—a socalled verrucous tuberculide. Special study of the latter proved it to be a sporotrichosis.—*La Presse Médicale.*

4. Technique and Interpretation of Dental Roentgenograms. Herbert McIntosh.
5. Preparation of Animal Food Proteins for Anaphylactic Tests. R. P. Wodehouse and J. M. D. Olmsted.
6. Body Types in Epileptics. Morgan B. Hodskins.

5. Preparation of Animal Food Proteins for Anaphylactic Tests.—R. P. Wodehouse and J. M. D. Olmsted state that the method used for making these preparations is the same as that used in the preparation of the vegetable food proteins but modified so as to be adaptable to meat and fish, since it yields the proteins in a highly concentrated form, and the preparations made by it are anaphylactogenically representative of the foods in the form in which they are usually eaten. In general the method is as follows: The material is ground very fine in a meat chopper and heated with approximately two volumes of water to 90° C. for one-half hour. The liquid is then strained off through cheesecloth and allowed to stand for a few days (using toluol as preservative); at the end of this time fats, if any, collect at the surface and are removed, the liquid is decanted from the sediment which usually settles out, and is filtered. Filtration is often slow and difficult on account of the gummy nature of the extracts. However, it is always possible to obtain eventually a clear or slightly opalescent filtrate. This filtrate is then exposed in large evaporating dishes upon the warm water bath before an electric fan until nearly dry (with chloroform as preservative). The result is usually a more or less hygroscopic gummy substance. This is then dissolved in as small an amount of water as possible and added to three or four volumes of 95 per cent. alcohol. This always causes the formation of a gummy or even syrupy precipitate which, probably on account of the hygroscopic nature of the peptones contained in it, shows a great avidity for water. Dehydration, however, can be completed by boiling and triturating in absolute alcohol, acetone and ether. The thorough washing given in these reagents also serves to remove all fats, oils and waxes. In removing the proteins from the baths of alcohol, acetone and ether, centrifugation is used in preference to filtration, since the process can thus be completed in much less time and with much less exposure to the atmosphere. This is important on account of the extremely hygroscopic nature of most of these preparations which in the presence of alcohol or acetone take up water so freely that an exposure of a few minutes is sufficient to render them liquid again; in this regard the animal food proteins show strong contrast to the vegetable food proteins. After the last ether bath the protein is removed to a sulphuric acid desiccator and drying is completed *in vacuo*. The result is always a friable powder which is readily soluble in water or dilute alkali.

The animal foods which we have so far prepared by this method are the following:

Pork, beef, lamb, chicken, haddock, cod, salmon, halibut, mackerel, lobster, oyster, clam (long necked). In making the preparation from oysters alone the general method was deviated from in that heat was not applied. The oysters were simply ground and macerated in cold water for several days (with toluol as preservative). This was deemed advisable because oysters are eaten raw as often as cooked.

New York Medical Journal.

July 21, 1917.

2. The Psychopathology of Prostitutes. Morris J. Karpas.
3. The Value of Sputum Cultures in the Diagnosis of Pulmonary Tuberculosis. John A. Roddy and David R. Brewer.
4. Human Anthrax. Joseph B. Bissell.
5. The Clinical Significance of a Fecal Analysis. Louis Winfield Kohn.
6. The Intravenous Use of Calcium Solutions as an Aid in the Treatment of Tuberculosis. Thomas J. Beasley.
7. Acute Appendicitis. Alexander Nicoll.
8. The Treatment of Locomotor Ataxia by the Maloney Method. Heinrich F. Wolf.

5. The Clinical Significance of a Fecal Analysis.—Louis Winfield Kohn states that test diets must be used for this purpose. An essential knowledge of a normal stool is necessary before it is possible to distinguish abnormal stools. He employs the Schmidt-Strasburger diet with some modifications:

Breakfast—Milk, tea, or cocoa (two cups), one soft boiled egg, two slices of bread and butter, and cereal—a small plate of strained oatmeal.

Dinner—A quarter of a pound of rare beef or chop well cut up, a large helping of mashed potatoes, and bread and butter.

Supper—One plate of soup, two soft boiled eggs, bread and butter. Cereal if desired.

This diet should as a rule be administered for one or two days in succession and sometimes longer, so as to obtain, if possible, a stool originating entirely therefrom. The second or third stool following the ingestion of the test diet will as a rule constitute the material desired for test purposes, particularly in those instances where a laxative has been given at least ten hours before the test diet was taken. In those cases where a laxative is contraindicated because of untoward symptoms as in intestinal catarrh or diarrhea of functional or organic nature or for other reasons, if not certain that the poper specimen of stool is obtained in the earlier evacuations, either extend the duration of the test dietary for a day or more, so as to give more time wherein additional specimens may be passed, or there can be administered at the beginning with the test diet certain coloring agents, harmless in action, which will serve as a marker in differentiating the preceding food waste from that of the test diet waste. After considering the color, reaction, consistence, quantity of residue, possible constituents, and odor of a normal stool, Kohn proceeds to the constituent inspection. Detailed macroscopical inspection by means of the use of a walnut-sized piece of excrement ground up in a small glass or porcelain mortar with a few c.c. of distilled water gradually added, and spread on a flat plat in a thin layer, with a dark background will give the correct method of procedure. There will be pin-head-sized debris, and cereal will appear as red brown pointlike remains, as will cocoa nibs. Vegetable or fruit will be small seeds, but in a normal stool no other signs will be found. In pathological specimens, on the other hand, many other ingredients may be noted. Numerous connective tissue and tendon remains from the chopped meat will appear as whitish yellow threadlike substances of solid consistence, and will speak for gastric disturbance as achylia gastrica, cancer extensive enough to have despoiled proper HCl and peptic secretion, or functional derangement involving secretion of motility either separately or jointly. An ill-acting nervous system may be back of this and be the underlying cause. Acetic acid may be employed on these shreds in order to determine their character. If mistaken for mucus, the acid will dissolve connective tissue, but applied to mucus causes it to coagulate. Muscle fibers resemble colored splinters of wood, and point to a disturbance in intestinal digestion, most probably a defect in tryptic activity, due to inefficient trypsin secretion or to a lack of bile secretion. Acute or chronic pancreatitis, cholecystitis, or cholelithiasis, or other diseases of the gallbladder or adjacent ducts, may be responsible for the nondigestion of muscle fibers. Potato remains in the stool as glassy, transparent granules and may be mistaken easily for mucus. This potato remains signify a disturbance in amylotic intestinal digestion, and the underlying condition may be functional or organic in nature. Fat remains may often show in the color of the stool, which will then be light or claylike and of putty consistency. The less fat there is in the stool the darker is its color apt to be, and *vice versa*. A deficiency of lipase or fat ferment in the pancreatic secretion or a lack of proper lipolytic action may account for this condition. Absence of bile will also produce nonfat digestion. Thin mucilaginous mucus is always present in normal stool, but when in any quantity, it has pathological significance. It may appear as flakes, indicating catarrhal intestinal disturbance. The smaller the flakes the greater the probability of catarrhal disturbance in

the upper portions of the large bowel, as the cecum, ascending colon, and transverse colon, but should the stool at the same time be liquid, then a hypermotility of the small and large bowel may exist and the flakes might come from the small intestine. The larger the mucus flakes, the nearer their origin in the lower portion of the large intestine. Flakes of pus indicate some ulcerative process. Blood, of course, means hemorrhage.

9. Perleche.—J. E. Lane announces that he does not know whether this condition is a rare one here, whether it is rarely seen because it causes little inconvenience and physicians are not consulted for it, or whether no one has thought it worth while to describe it because it is of so little consequence. In New Haven, Conn., it appears to be quite common, as he has seen from forty to fifty cases in a year and a half. Although occasionally found in adults, this condition is pre-eminently one of infancy and childhood. It is an affection of the labial commissures, almost always bilateral, and usually rather closely limited to the commissures. As it progresses, the process extends for a varying distance toward the center of the lips, and usually extends a little on to the skin surface and on to the true mucous membrane of the inner side of the lips. At the beginning of the disease the epithelium is smooth and whitish, with a mother of pearl tinge. As it progresses the epithelium becomes macerated, a little thickened, and loses most of the mother of pearl color. Small transverse fissures appear, which show a red base, if the lips are stretched, but which do not reach the lower layers of the epidermis, and which do not bleed readily even if rubbed. In some cases there is slight erosion, but the surface is ordinarily not denuded. According to Lane this condition is not an ulceration, and there is no swelling of the lips connected with it, and little or no inflammatory area around the lesions. If treated the disease is usually cured in two or three weeks, while if left to itself there is usually spontaneous cure in a month or so, unless there is reinfection, but in some cases it is of indefinite duration. In the mild cases of perleche there are no symptoms at all. In the fully developed cases there is a slight feeling of irritation which causes the child to continually run the tongue over the lesions. It is from this sign that the disease derives its name. There is never enough discomfort to cause the child to rub or pick the lesions. According to investigators, perleche is caused by the *Streptococcus plicatilis*. It is a highly contagious disease, and common drinking vessels are the most frequent vehicles of transmission. Kissing, the use of common pencils, handkerchiefs, and towels, are also other means of contagion. While this condition may be confused with other common skin lesions, syphilis is the chief condition for differential diagnosis. The lesion of perleche and the mucous patch strongly resemble each the other. A dark field or the Wassermann clears up this difficulty. Treatment consists in prophylactic measures. Prompt cure is effected by painting the lesions daily or every other day with a 10 per cent. solution of silver nitrate, a diluted tincture of iodine, and the copper sulphate of the alum pencil. Sabouraud recommends in addition an antiseptic mouth wash, but this is hardly needed in most cases. Auché found a 5 per cent. solution of chromic acid efficient in the few cases that resisted the milder treatments mentioned.

2. Reflections on the Limitations of Vaccine Treatment.—Robert J. Rowlette states that the experience of the present war puts beyond all question the value of preventive vaccine inoculation against the enteric diseases. In ordinary home medicine, too, experience has shown the efficacy of this method, particularly in the results of inoculation against recurrent catarrhs of the respiratory organs. A vaccine is not a new ally in the fight between the parasite and the host, assisting the latter to destroy the former; it is only a stimulus to the body to exert to the full its natural powers of resistance and protection. Of itself it can do nothing. The specific action of vaccines is different from the same action of drugs, as vaccines are only active against bacteria mediately in that they stimulate the production of bodies which possess special destructive powers toward particular organisms. Vaccines are, therefore, in a sense, only specific at second hand. In extreme bodily exhaustion this stimulation cannot be produced and the vaccine fails; moreover, in cases where it does not fail, its success is proportional to the power of the tissues to respond to its call. To expect uniform success from vaccine is, according to Rowlette, as unreasonable as to suppose that the body can never fail in its defense against attack. It follows that the cases in which the best results may be expected from vaccine treatment are those in which (1) the body has not yet lost its natural power of resisting infection, and (2) in which there has not been great tissue change. With reference to the scope of vaccine treatment, Rowlette states that bearing in mind the limitations here given, vaccines may be employed in every infective disease due to bacterial origin in which the bacterial cause can be discovered. The acuteness or chronicity of the condition is beside the point, though it may have much to do with the method of administration. Since vaccines are specific, a correct bacteriological diagnosis is necessary. As a result, many times a mixed vaccine has to be employed. No greater misconception can exist than the notion that vaccine treatment is incompatible with the use of other methods of treatment. On the contrary, the best results from this method of treatment are rarely obtained unless full use is made of whatever concomitant measures experience may offer. Few drugs are inimical to the action of vaccines, except those depressing the natural resistive powers of the body, which are therefore contraindicated when vac-

cines are to be employed. Of these the only drug in common use is alcohol, the employment of which in septic diseases should by now be obsolete except under rare conditions. In surgical conditions, operative measures, or anything else that surgical knowledge suggests should, of course, be practised when required. The only precaution to be observed is to withhold inoculations in immediate proximity to any manipulative proceeding which may give rise to autoinoculation. Otherwise vaccines, of course, act in their normal manner of increasing the protective power of the body. Rowlette states further that much misjudgment of vaccine treatment by the profession has been due to the treatment being so largely committed to men unaccustomed to clinical work. It cannot, however, remain in the hands of a special class. As an important branch of therapeutics it must become familiar to every practitioner. No student can be considered to have gained a sufficient knowledge of therapeutics who has not become familiar with both the doctrine of immunity and the practice of immunization. In this way vaccine treatment will come to take its proper place—not as something peculiar and special, but as an essential part of the treatment of infective disorders of bacterial origin.

5. A New Culture Medium for the Gonococcus.—D. Thomson states that there has been recently a great need for a satisfactory culture medium for the gonococcus, not only for diagnostic purposes, but also for the manufacture of gonococcal vaccines. He points out the defects in the media now employed, which he gives as follows: The growth is by no means profuse; the medium is not clear, and the gonococcus growth is not seen clearly; for vaccine purposes blood agar is very unsatisfactory because the water of condensation at the bottom of the tube contains a dark brown débris of broken-down red cells, and the gonococcus emulsion mixed with the above is colored and full of débris which renders it difficult to standardize; also, the emulsion obtained from the trypsinized pea extract cultures, though yellow in color, is quite unsatisfactory for the same reason, and does not appeal to the writer as a natural one, because by subculture the germ may lose its antigenic properties and become less potent for vaccine purposes. Thomson first removed the red corpuscles from the human blood and used the plasma. It was found that the gonococci grew as well on plasma agar in the proportion of one of plasma to four of agar as they did when the corpuscles were present. The growth, however, was not profuse, but experimentation corrected this by the use of the following medium: (1) Prepare nutrient agar (2.5 per cent.) in the ordinary way with bouillon and Witte's peptone (1 per cent.), and render it + 6 acid. (2) Instead of adding to this 0.5 per cent. sodium chloride, as is usual, add all the salts natural to the human blood (as in Ringer's solution)—namely: Sodium chloride 9 grams, calcium chloride 0.25 gram, and potassium chloride 0.42 gram per liter. (3) Add glucose 2.5 per cent. This addition in some manner renders the growth much more profuse. (4) The nutrient agar with salts and glucose is then tubed, about 4 c.c. being added to each test tube. (5) The sterile tubed agar is melted in boiling water, and after allowing it to cool to about 50° C., add 1 c.c. of human plasma to each tube and mix thoroughly by rolling the tube between the palms. Allow the medium to solidify in a sloping position. For plating, the contents of three tubes may be added to a Petri dish. To obtain human plasma the following method was employed: In all venereal hospitals blood is frequently drawn off from the veins of syphilitic patients into test tubes for the Wassermann test. In consequence, the source of human plasma is always available. When a supply of plasma is required, draw off three-quarters of a test-tube-full of blood with all sterile precautions. Have a sterile centrifugal tube ready, containing 2 c.c. of a 2 per cent. solution of sodium citrate. Fill up this centrifugal tube with the freshly drawn blood. Plug it with a sterile cork (keep the corks in alcohol and burn off the alcohol before plugging) and centrifugalize. When the corpuscles are driven down, pipette off the supernatant plasma with a sterile 10 c.c. pipette and add 1 c.c. to each tube of agar as indicated above. If the test tube of blood is three-quarters full there is sufficient left for the Wassermann test after filling the centrifugal tube. It is immaterial, according to Thomson, whether the patient is being treated or not with arsenic or mercury. This medium is beautifully clear and transparent, and it is as natural as possible. The growth is very profuse, even after eighteen hours, and the emulsion obtained is white. When counting a vaccine, a culture not more than one day old should be used, since after this time many of the gonococci begin to autolyze, and the count would be too low. After making up standard emulsions of, say, 1,000 and 500 million gonococci per c.c., Thomson states that the strength of other emulsions can be estimated directly by diluting and matching them with the standard.

7. Flies and Bacillary Enteritis.—William Nicoll, after thorough experimentation, states that it has been fairly conclusively proved: That under experimental conditions flies can readily carry and disseminate certain pathogenic organisms. That these organisms are not infrequently met with in flies under natural conditions, particularly in association with outbreaks of infectious diseases. That organisms producing bacillary enteritis are to be met with not infrequently in flies under natural conditions. That a considerable number of organisms resembling enteritis bacilli occur frequently in flies in the natural state, and that the utmost care is necessary in discriminating between these and the true enteritis producing organisms.

Variations in Cholesterinemia During the Menstrual Cycle.—Chauffard states the prevalent opinion that the corpus luteum is a temporary organ of great importance, having very complex functions and a histological structure which suggests that of the glands of internal secretion (this was remarked as long ago as 1898). In 1911-12 the author and two others discovered in this body, in addition to lecithins, nonphosporated lipoids, especially cholesterin ethers. In other words, the corpus luteum is a structure for the manufacture of cholesterin. But fluctuations in cholesterinemia have been studied chiefly in gravidæ, while from other angles the corpus luteum of menstruation has been the object of study. Recently, however, cholesterinemia during the menstrual cycle has been studied by Gonalons of Buenos Aires. Curves plotted by him show elevation during menstruation, but in the majority of cases the maximum is about six days before menstruation, when there is a sudden rise with immediate fall; and a second rise, held during menstruation. Less common is a moderate elevation with equilibrium several days before menstruation, and a sudden rise when the latter appears. The crux of the matter lies in the ability of organs other than the corpus luteum to produce cholesterin. Gonalons believes that the latter body is formed in the adrenals, thyroid, etc., as well as the ovary. The author has never denied the existence of this possibility. The subject of interaction between several endocrine glands and fluctuations in cholesterinemia is highly complicated. The author sees dimly a partial explanation of the fact that gallstones occur by preference in women, *i.e.* their formation is favored by the hypercholesterinemia of menstruation and gestation, or in other words, by ovarian activity.

Sulphur and Eucalyptol in Skin Diseases.—Bory has for many years been interested in the systematic use of these two substances in a variety of dermatoses. Both have notable value as local applications, their action being attributable largely to antiseptic and germicidal properties. In 1907 the author conceived

the idea of injecting these substances beneath the skin. At that time colloidal sulphur had come into use as a remedy. The author's experience with it was not satisfactory, and he substituted a mixture of precipitated sulphur and oil of sesame (the latter having proved superior to liquid petroleum). In view of Gaucher's theory that psoriasis is often a paratuberculous affection, the author was the more encouraged to test sulphur and incidentally eucalyptol addition. In a small number of cases the oleaginous suspension of sulphur and eucalyptol, injected into the patients' gluteal muscles, produced an astonishing result. In some instances no local treatment was applied; while in others eucalyptol in collodion, sulphur, and calomel seemed to be useful additions. Whatever the intimate nature of psoriasis there are many data to show that it has a parasitic causal factor, which perhaps explains why it benefits under eucalyptol and sulphur.

La Presse Médicale.

June 18, 1917.

Discrete Costodiaphragmatitis in the Army.—Mouriquand describes a largely radiographic affection of such common incidence among the troops that over 150 cases were recognized in six months in two medical services. Most of them were recognized before radiography, but in a certain number the screen furnished the sole evidence. In civil practice this lesion might not cause the subject much discomfort, but it is otherwise with soldiers in a campaign, with their arduous physical duties. That this condition is readily overlooked depends largely on the unfamiliarity of the profession with the bases of the thorax. The socalled costodiaphragmatic sinus has some anatomical but no pathological status. After many efforts the author and his colleagues have developed a symptomatology for affections of the "extreme base," which in turn takes its start from a mean or average norm. A so-called basilar line extends between two costomuscular points, which are seated from 8 to 9 cm. on either side of the spine. Here the last rib is felt in contact with the sacrolumbar mass of muscles. Using this as a datum line, the author, by means of the stethoscope, locates the point at which the vesicular murmur becomes audible, and also the area of dullness on percussion. This dead space measures about 3.6 cm. in height. When it is inflamed the patient has costodiaphragmatitis, which in at least 50 per cent. of all cases is a sequel of tuberculous pleurisy. In other cases the affection is a sequel to purulent pleurisy, hemothorax, simple trauma, pneumonia, etc. The condition often coexists with advanced pulmonary tuberculosis, but naturally such cases have no place here. In the majority of the author's cases the lesion was uncomplicated. It sometimes occurs in the emphysematous, and is then very difficult to discover. In making the diagnosis the screen is of great value, but auscultation and percussion are often sufficient, because the area of normal dullness is increased upwards and the vesicular murmur correspondingly diminished. Inflammation of the costodiaphragmatic sinus is followed by adhesions, and these are largely responsible for the alterations found on physical diagnosis. These lesions tend with time to undergo spontaneous involution, but the subject is disqualified for the time being. The rational treatment comprises respiratory gymnastics and heliotherapy.

The Sensitive Achillean Sign in Sciatica, Etc.—Revault D'Allonnes states that the war has made the sciatic nerve a much-discussed structure, aside from its injuries. Simple sciatica from exposure in the trenches, sciatica as a phenomenon of malarial origin in the Balkans, psychogenic sciatica all loom up among purely medical affections. The number and variety of traumatisms involving the nerve is without limit. Our symptomatology of the nerve is being enriched day by day. The classic symptoms no longer suffice for diagnosis, because of their inconstancy. Valleix's tender points are often absent, or only doubtfully present. The same may be said truthfully of the signs of Lasègue and Bonnet. Some of the other classic signs have greater diagnostic value. Among these is the sign of Bondet (not to be confounded with Bonnet). Charcot's sign, and some of the minor criteria, possess value. Space does not permit the recapitulation of all of these phenomena. Really valuable evidence, depending on the trophic changes in the muscles and skin supplied by the nerve, appear too late to be of service in treatment. The author now gives a new sign which he holds to be pathognomonic. He pinches the tendon Achilles in order to determine the conductivity of the nerve to sensory impulses, as well as the degree of sensitiveness of the tendon itself. He has examined 110 cases, divided almost equally between medical and surgical. To begin with, if the nerve has been completely severed, pinching is followed by no results of any kind. Bilateral anesthesia occurs in various types of neuritis (polyneuritis), not only during the status, but even after slight improvement. When the latter has become considerable hyperalgesia is substituted. The same sensation appears in a nerve partly severed, and when total separation has been repaired by suture. In ordinary neuralgia (sciatica) hyperalgesia is also present in the majority of cases. In traumatic paralysis it is very rare. The rationale of the various results obtained by pinching the tendon, require coordination.

Correspondenzblatt für Schweizer Aerzte.

June 16, 1917.

Acquired Tolerance of the Heat Center to Pyretogenous Substances.—Cloetta raises the following question: Suppose that the organism is exposed daily to noxæ which excite fever, does the febrile reaction produced tend to increase, diminish, or remain the same? When we see the same temperature develop daily are we justified in the inference that the same quantity or quality of fever producing substance enters the blood daily? Is a rise or fall presumption that this amount has been increased or diminished? May there not be an acquired hypersensitiveness or tolerance which could be responsible for elevations and depressions? These questions have a marked practical bearing, but cannot be answered from either the clinic or laboratory without leaving the field of ordinary research on immunity and anaphylaxis. In other words, the conception of antibodies cannot aid in the solution of the problem. A substance must be tested which does not give rise to such. In beta-tetrahydronaphthylamin (and some of its derivatives) we have a substance which acts on the heat center and causes temperature rise. We therefore may inject daily a fixed quantity and record the readings of the thermometer. The substance must be injected into a vein and very deliberately, in order to avoid severe collateral results, as it has the property of stimulating the motor nerve centers. The temperature begins to go up in 15 minutes, reaches a maximum in one and one-half hours, and then slowly falls. Next day the animal's temperature is normal. In other words, we have brought about a single febrile movement. When a rabbit was selected for a continuous test it was found that injections made daily caused the following temperature elevations: Thus on June 14 the maximum was 0.8° C.; on the 17th it was 1.3°; 27th, 1.4°; July 5, 1.2°; 12th, 1.0 ; 24th, 1.2°. These slight variations are not significant, for the normal temperature itself is subject to fluctuations. For all practical purposes the fever was constant for the two months' experiment period as carried out on two rabbits. Hence, the heat center cannot be made more or less sensitive to this substance.

Emetine and Hepatic Abscess.—Paravicini states that not long ago emetine was used only as an emetic and expectorant. Today it is one of our most many-sided and efficient remedies. Used extensively in the United States for pyorrhea alveolaris, it has been found incidentally to be of value in psoriasis. Ipecac itself is an old remedy for amebic dysentery and the hemoptysis of tuberculosis, and emetine hydrochloride injected into the muscles for the same conditions represents an advance. In the treatment of cholera emetine has been used with 73 per cent. recoveries. The action of emetine in amebic dysentery, hepatitis, and hepatic abscess, may be nothing short of wonderful. The author reports a case of amebic infection with hepatic abscess and an intermittent type of fever cured by emetine.

Book Reviews.

THE METHOD OF ENZYME ACTION. By JAMES BEATTY, M.A., M.D., D.P.H., with introduction by Professor E. H. STARLING, M.D., Sc.D., F.R.S. Price, $1.75 net. Philadelphia: P. Blakiston's Son & Co., 1917.

THIS small monograph contains an excellent review of the general nature of catalysis and enzyme action and a new hypothesis of the processes underlying the action of enzymes upon the substrates. No attempt has been made to adduce any experimental proof of the hypothesis thus brought forward, but the whole book is suggestive and interesting to the biological chemist.

PHYSICAL CHEMISTRY OF VITAL PHENOMENA. For students and investigators in the biological and medical sciences. By J. F. MCCLENDON, Assistant Professor of Physiology in the University of Minnesota. Price, $2.00 net. Princeton: Princeton University Press, 1917.

THE application of physical methods to the quantitative study of chemical reactions is of fairly recent date, most of the work having been accomplished within the past twenty years. Despite the shortness of this period, however, the amount of valuable material which has been placed at the disposal of the physician is enormous, and our understanding of the chemical processes underlying some of the most important clinical manifestations of disease has been greatly clarified by these studies. It is necessary to mention only the question of acidosis, which was originally thought to be connected chiefly with the terminal stages of diabetes, but is now known to be a phenomenon connected with many other diseases, notably cardiac lesions and some of the nutritional disorders of childhood. The simplified chemical methods which have been devised for determining the degree of acidosis are even now finding clinical application. Our understanding, also, of the fundamental principles of dyspnea and apnea have been much helped by quantitative chemical analyses.

The whole question of the colloidal condition has been much clarified of late and many otherwise extremely obscure phenomena in medicine have been explained. The study of the relation of the degree of ionization to the rate of disinfecting action of certain well known chemicals has shown that many of these are ineffective and has led to the devising of new synthetic compounds of much greater efficiency. Even the factors underlying the artificial production of cell division, first observed by Hertwig and Morgan, and later expanded by Loeb, have received physicochemical explanations. Anesthetics, also, have been studied by these methods and useful information has been obtained. These are a few of the subjects touched upon in this admirable series of lectures by one who has made many personal contributions to chemistry. The mathematical treatment has been expurgated sufficiently to meet the capacity of the average college graduate, whose mathematical quanta usually carry a negative sign. If the physician of this generation cannot understand the simplest principles of the underlying science of his trade, it might be well for those who are educating the physician of the future to see that his mathematical knowledge extends beyond the ability to add and subtract. The information contained in this book should be made a part of the education of every medical student.

THE INTERNAL SECRETIONS. Their Physiology and Application to Pathology. By E. GLEY, M.D., Professor of Physiology in the College of France. Translated from the French and Edited by MAURICE FISHBERG, M.D., Clinical Professor of Medicine, New York University and Bellevue Hospital Medical College. Price, $2.00 net. New York: Paul B. Hoeber, 1917.

ONE of the predominating fads of the present day is endocrine gland therapy, which during the past three or four years has suffered an enthusiastic but often rather thoughtless revival. Of course, the chief trouble is that we know so little about the physiology and pathology of these organs that any rational therapy is difficult. It is true that advances are being made continually in this field, and we are gradually coming to apply and to make our preparations of the glands of internal secretion with much more judgment and reason. Gley's work on the history and physiology of these organs is well known and justly valued in its native language, so that an adequate and sympathetic translation is very welcome. It is "a concise history of the subject as well as a critical examination of the main facts on which the doctrine of internal secretions is based." Conservative, scientific, and illuminating, it points out clearly what we know in this field and, what is still more valuable, it lays down broad physiological tenets on which all our knowledge must necessarily be based. It is very gratifying that this excellent translation is now available and it should prove a popular work.

CITY MILK SUPPLY. By HOWARD NEWTON PARKER, formerly Health Officer of Montclair, N. J., lately Instructor in Municipal and Sanitary Dairying at the University of Illinois; Member of the International Association of Dairy and Milk Inspectors. Price, $5.00. New York: McGraw Hill Book Publishing Co., Inc.; London: Hill Publishing Co., 1917.

"THE milk business is not the farmer's business, nor the contractor's, nor yet the consumer's; it is the community's business, and unless the members of the community work together for good milk they will never get it." Mr. Parker carries his account of the city milk supply from its beginning to its end and in great detail. The book is extremely interesting and well written. Methods of causing dirty milk and of making clean milk are carefully gone into, the care of cattle, the construction of barns, the handling of the milk from the milking to its ultimate disposal. The cost of various details in the work is given, and finally a discussion of methods of control of public milk supply.

THE MEDICAL CLINICS OF CHICAGO. May, 1917. Volume II, Number 6. Published bi-monthly. Price per year, $8.00. Philadelphia and London: W. B. Saunders Company.

THIS number of the Medical Clinics finishes the second volume of this publication. A brief glance over the numbers which have appeared shows that there has been a gradual change in the form in which the presentations have been made. The number of contributors to each number has been somewhat increased, so that we have thirteen in this issue, while at the same time the number of cases presented at each clinic has been diminished until we have here but one case shown by each man. A comparison of the first number with the latest one shows a very marked improvement in this respect. The cases receive much more adequate consideration and the value of the publication is thereby considerably increased. It is for this reason that a somewhat grudging approval which was apparent at the outset has become a general commendation of the Medical Clinics, so much so that it is even, at times, enthusiastic. It is probably more true of this than of any other similar publication with which we are familiar, that the latest number is the best.

THE PRACTICAL MEDICINE SERIES. Under the general editorial charge of CHARLES L. MIX, A.M., M.D., Professor of Physical Diagnosis in the Northwestern Medical School. Volume II, GENERAL SURGERY, edited by ALBERT J. OCHSNER, M.D., F.R.M.S., LL.D., F.A.C.S., Surgeon-in-Chief Augustana and St. Mary's of Nazareth Hospitals; Professor of Surgery in the Medical Department of the State University of Illinois. Series 1917. Price, $2.00. Chicago: The Year Book Publishers.

THIS volume follows the same general plan as its predecessors and gives an epitome of surgical literature appearing during the year 1916. In the introduction Ochsner eulogizes at great length the previous editor, the late John B. Murphy, who had edited the volume on general surgery for many years. The surgery of the various organs and regions of the body receives adequate attention. In addition, considerable space is given to articles concerned with the treatment of infected wounds, wound healing, gas gangrene, tetanus, and other subjects bearing on war surgery—a fact which should make this volume of especial interest to those soon to become army surgeons. The general practitioner who occasionally cares for surgical cases as well as the specialist should find this volume well worth reading.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held April 20, 1917.

THE PRESIDENT, DR. J. BENTLEY SQUIER, IN THE CHAIR.

Resolutions for Defeat of Chiropractic Bill.—Resolutions were adopted by the Society providing that immediate steps be taken to defeat a bill providing for the license of chiropractors which had been reported out of the rules committee and would come up for vote in the Assembly on April 23.

Resolution for Protection of Practice of Medical Men at the Front.—The Society adopted a set of resolutions providing for the appointment of a committee who should find physicians to care for the practice of those going into military service and providing that physicians assuming the care of the practice of absentees should turn over to such persons as the absentees should designate 50 per cent. of all collections from the practices of such absentees; that accounts be submitted monthly, and that the practice of an absentee be returned to him intact on his return.

Obstructive Jaundice.—Dr. CHARLES GORDON HEYD read this paper, in which he gave a résumé of the pathological affections of which jaundice was a symptom. He stated that according to McCarty, the gallbladder, liver, pancreas, and stomach were embryologically, physiologically, and pathologically closely related and should be considered as one physiological system. Jaundice was such a protean and variable symptom and was associated with so many conditions that individually it offered little in the way of diagnostic value, but by means of its correlation with the history, physical examination, the chemical examination of the urine, stool, and blood, and variations in the functions of the organs of the right upper quadrant, it was possible to make a surgical diagnosis. In its ultimate analysis jaundice was an interference with the delivery of bile from the liver to the intestinal tract. Jaundice was essentially an obstructive phenomenon. In regard to the production of jaundice we spoke of (1) intrinsic internal or luminal occlusion which, except for parasites and hydatid cysts, meant calculous disease of the common duct; (2) mural occlusion, either inflammation of the duct wall or stricture or neoplasms and (3) extrinsic or external occlusion, either by invasion or compression from lesions of tissues adjacent to the biliary apparatus from the portal fissure to its duodenal termination. Statistical inquiry and analysis of a large series of cases exhibiting jaundice demonstrated that according to its frequency jaundice might be classified in the following order: (1) gallstones, (2) catarrhal jaundice, (3) cancer of the liver, (4) cirrhosis, (5) cancer of the bile ducts and gallbladder and (6) cancer of the pancreas. Of all cases of obstructive jaundice, 97 per cent. would be included in these six divisions. In conclusion Dr. Heyd said that the diagnostic value of obstructive jaundice depended upon its association with one or the other of two main symptom groups: A jaundice with colic, with chills, fever and sweat, with leucocytosis, with intermittency, with a previous history of right upper quadrant inflammation, with a nonpalpable gallbladder, with stercobilin and intermittent acholic stools represented luminal obstructive jaundice and, barring the rare accident of worms, parasites, and hydatic cysts, was a calculus disease of the common bile duct. A jaundice without colic, without chills, fever and sweat, without leucocytosis, which never intermitted, which was persistent and continuous, increasing and deepening in severity, with a palpable gallbladder, without stercobilin in the feces and with chronic acholic stools represented an extrinsic obstructive jaundice and was a neoplastic condition outside of the common duct.

Dr. WILLY MEYER emphasized the points that enabled one to make a differential diagnosis between calculous disease of the common bile duct and a neoplastic condition outside of the common duct, and reviewed the symptoms that pointed to tumor of the pancreas. In operation on these cases the thing to be feared was secondary hemorrhage. He had learned that in cases of chronic jaundice it was advisable to investigate the coagulation time of the blood. Several theories had been advanced to explain the change in the coagulation time of the blood in some cases of chronic jaundice. One of these attributed it to the increase of bile salts in the blood, but an increase of bile salts sufficient to effect such a change was simply impossible. Personally, he believed the ductless glands were responsible for the change, just as he believed they were involved in the etiology of hemophilia and thromboangitis which he preferred to call thrombophilia. When a patient had a lengthened coagulation time and there was reason to fear secondary hemorrhage it was the duty of the surgeon to prepare against this emergency by giving an injection of blood serum before the operation. Human blood serum was preferable to horse serum for this purpose. A large preliminary dose would prevent parenchymatous hemorrhage.

Dr. CHARLES A. ELSBERG said that Dr. Heyd and Dr. Meyer had so thoroughly covered the subject that there was little left for him to say. He had intended to speak of hemorrhage, as he had investigated this subject a number of years ago. He could not agree that it was due to a ductless gland condition because of a number of clinical facts. That hemorrhage was apt to occur in the patients with jaundice who had both an obstruction of the common duct and of the pancreatic duct was shown by both clinical and experimental observations. Usually there was no parenchymatous oozing within twenty-four hours after the operation; the worst hemorrhages were likely to occur six, seven or eight days after the operation. Such hemorrhage was likely to occur at a time when the patient was apparently doing exceedingly well; absolutely nothing would control the oozing; from the time a patient began to ooze that patient was lost. When there was an obstruction of the common and pancreatic ducts one should begin the serum treatment at once after the operation, in order to prevent dangerous and almost regularly fatal bleeding. Since working on this principle Dr. Elsberg stated that he had seen less of this postoperative hemorrhage than before. Mayo Robson had made the distinction between the green color of the skin in obstructive jaundice due to malignant disease and dark yellow color due to obstructive jaundice from calculi, but there were some patients whose skin was of a light canary color. A light canary colored skin was quite characteristic of common duct and pancreatic duct obstrution; this they had repeatedly confirmed at operation. This was a point to which from the diagnostic standpoint sufficient attention had not been paid.

Dr. DUDLEY ROBERTS said that while he had seen a great deal of diverticulitis of the colon, he had seen very little acute diverticulitis; he had seen only a few cases that had gone on to acute rupture. Dr. Erdmann's statistics were quite different from his in that Dr. Erdmann had found this condition most frequently in individuals between the ages of 40 and 45 years, while in his experience nearly all these cases were 60 years of age or over. When the condition was found in younger persons, it was probably congenital and this was the reason why it was so liable to rupture. He felt convinced that diverticula were of quite frequent occurrence, and had about come to the conclusion that very many "pot-bellied" individuals had diverticula. While he thought the condition might exist without causing a great deal of harm it was nevertheless important in as much as it might furnish a basis for the development of cancer or benign obstruction. Mayo in a series of cases reported that in only four instances could it be definitely shown that cancer had developed as the result of multiple diverticula, while only last week the speaker had seen two cases in which malignancy had apparently resulted from this condition.

Patients suffering from diverticula usually complained of pain on the left side and sometimes attacks of abdominal colic. He had seen only two patients who had complained of rectal tenesmus and the passage of mucous. He did not therefore consider these symptoms as of frequent occurrence in this class of patients. When the lumen of the gut was narrowed and there were a number of diverticula and a peridiverticulitis proven, the speaker did not feel that the case was necessarily one for operation. One could do much by the medical treatment of these cases. The first thing to do in all

cases was to stop laxatives and purgatives and to try to keep the pockets filled with bismuth in the expectation that they would thus be kept free from accumulations of material that was likely to undergo putrefactive changes.

Dr. Roberts gave a lantern slide demonstration of diverticula.

Dr. CHARLES N. DOWD said he had studied the records of cases of diverticulitis and had found that there were 17 such cases treated either by his associates or by himself, and he believed that these cases gave a fair indication of the way in which the disease was likely to be seen at the present time. Most of the cases had gone on to definite abscess formation before surgical aid had been called for, and those cases which had reached a stage of local abscess formation were the ones which gave the best results. Of the 17 cases, 11 were cured, two improved, and four had died. Two of the cured cases had been treated by intestinal resection; the remaining nine were treated by the opening of localized abscesses. These patients, as a rule, did not stand extensive abdominal operations well. The large intestine was not well adapted to extensive one-stage resections. When resection was necessary, it was usually much better to do a two-stage operation having the two legs of intestine come to the surface like a double-barrelled gun, as advocated by Mikulicz. He reduced his mortality nearly one half by employing this method of operation. It was somewhat remarkable that so many of the local abscess cases had recovered under simple incision and drainage. There had been several interesting experiences in this series. In one instance what had seemed to be a diverticulitis proved to be an appendicitis with the appendix on the left side; another instance, two patients who were in the ward at the same time showed severe definite symptoms of diverticulitis, but the inflammatory mass subsided and recovery resulted in both instances. In considering statistics, one must judge results by learning the time at which operation was done. Early operations were naturally much more favorable than operations for people who were already suffering from general peritonitis.

A Simplified Technique in Tuberculin Administration.—Dr. ELLIS BONIME presented this communication. He said he had obtained his experience with tuberculin largely in ambulatory cases and was convinced of its far reaching effects if it could be administered with safety by the intelligent general practitioner. So he had endeavored to devise a simple method of tuberculin administration which retained the principal elements necessary for its therapeutic effect. He had finally succeeded in elaborating the method which he would explain. Before going into details as to the technique he wished to say a word or two about the choice of tuberculin and the method of making the dilutions. The greatest value could be derived from long practice in the use of one tuberculin and making it applicable to exceptional cases, rather than endeavoring to find a tuberculin to fit each particular case. In making dilutions, simplicity was the aim. Directions for making dilutions had been unnecessarily complicated. Using as diluent 0.5 per cent. phenol in normal saline, with the same tuberculin syringe that they used in treatment, they made five dilutions of the original tuberculin. By drawing 0.9 c.c. of the diluent into the syringe followed by 0.1 c.c. of tuberculin, the first dilution was made and placed in the container marked I. By drawing 0.9 c.c. of the diluent into the syringe followed by 0.1 c.c. of dilution I, the second dilution was made and placed in the container marked II. By drawing 0.9 c.c. of the diluent into the syringe followed by 0.1 of dilution II, the third dilution was made and placed in the container marked III. By drawing 0.9 c.c. of the diluent into the syringe followed by 0.1 c.c. of dilution III, the fourth dilution was made and placed in the container marked IV. By drawing 0.9 c.c. of the diluent into the syringe followed by 0.1 c.c. of dilution IV, the fifth dilution was made and placed in container marked V. The dosage began with an amount of tuberculin less than would produce a reaction. This dose was subsequently increased by a definite but very small amount, and the amount of increase also increased by a very small amount and at regular intervals. The amount of dose increase was only sufficient to control the amount of tolerance gained by the preceding doses. And the amount of the increase would control the difference between the amount of tuberculin administered and the maximum amount the individual could tolerate. The progressively larger increase in the dose thus brought about would eventually produce a constitutional reaction. This reaction would necessarily be mild, as it was produced by the smallest amount of tuberculin required to produce such a reaction in that individual. By increasing the intervals after such reactions, and decreasing the dose by a small amount, they were certain that they were using a quantity of tuberculin coinciding with the maximum of tolerance of the individual, or that dosage which alone would produce the ideal therapeutic effect. Tuberculin injections should be given twice weekly. In concluding treatment it was advisable in a great many cases, especially in bone and joint disease, to produce a bacillary immunity before they discharged the patient. Those who finally succumbed to the disease were those who had acquired the idiosyncrasy to the protean poison, or the hypersusceptibility after an initial infection. By the use of tuberculin they could both detect that hypersusceptibility and overcome it before a recurrence of the disease could take place.

Dr. JOSEPH MUIR said one read on the program a "Simplified Method for the Administration of Tuberculin." That looked well on the program but he was not impressed with the simplicity of the method as described. He had been employing tuberculin but not in ambulatory cases. He thought it was impossible to know when one obtained a reaction unless the patient was kept under close observation. He had been using tuberculin since 1895 when they did not know how to use it and felt satisfied of the great danger that, under its use, a consolidation might become a cavity and a local infection a miliary tuberculosis. As employed by Trudeau and Hamburger it was much safer than formerly but he could not agree that the method presented had simplified the administration of tuberculin to such an extent that it was safe for the treatment of ambulatory cases. If one examined patients who had received the tuberculin treatment, and who did not show a reaction in the form of an elevation of temperature and malaise, with the stethoscope it might be found that an increased exudate or a slight inflammatory reaction had occurred. There might not be so great danger of a reaction in gland and bone tuberculosis, but he felt sure that the pulmonary cases required very careful watching when under tuberculin treatment.

Dr. THOMPSON T. SWEENEY asked for an expression of opinion as to the value of Von Ruck's vaccines.

Dr. FRITZ NEUMANN said he had been using a similar simplified method, not using the old tuberculin but the bacillary emulsion, for eight years, on ambulatory cases. He had given thousands of injections but had never obtained a general reaction, though occasionally he had observed a local reaction. Sometimes there would be a slight rise in temperature of one or two-tenths of a degree the day after the injection was given. In order to get accurate records of the temperature he had every patient for a week before beginning the injections take his own temperature four times a day and put it down on a chart, and he had noticed that it was very rarely that there was a reaction after using the bacillary emulsion. He had had just as good results in moderately advanced cases as in the earlier cases and he had observed no change from a consolidation to a cavity. He believed the bacillary emulsion could be used in all moderately advanced and incipient cases.

Dr. BONIME, in closing the discussion, said the first speaker mentioned the impossibility of noting the reaction after the administration of tuberculin as a change occurred that could only be noted by the stethoscope. Such a change was a focal reaction, and was the basis for any good result as it was a focal hyperemia that starts the healing process. The patient got a focal reaction after every sufficient dose of tuberculin, and there should be no fear of this reaction. Dr. Bonime said he had no experience with von Ruck's vaccine, but that if a physician obtained good results with this preparation he should continue with its use. The more experience one had with a particular preparation, the better the results. The doctor who gave his experience with bacillary emulsion said that it did not give the char-

acteristic reaction that old tuberculin did. Dr. Bonime's experience was quite the contrary. The reason old tuberculin was chosen for the beginning of treatment was because old tuberculin was not as likely to produce a severe reaction as bacillary emulsion. After old tuberculin has been administered until the hypersusceptibility was over, no reaction could occur. Treatment was concluded with bacillary emulsion, which was used in as large doses and in the same way as vaccine was used. No patient could be treated with tuberculin without the regular temperature records, as they were the only guide as to whether a reaction had occurred or not. As no two patients reacted to the same amount of tuberculin, no two treatment charts ever looked alike. By following the indications and the method described, the dosage adjusted itself to each individual case.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held March 2, 1917.

Dr. JOHN DOUGLAS IN THE CHAIR.

Mycosis Fungoides; Case of a Tumor Stage after Treatment.—Dr. ARTHUR F. HOLDING presented this patient and gave a lantern demonstration of the case before and after treatment, and also a photomicrograph. This patient had been ill for nine years, had been seen in the pre-tumor stages of the disease by dermatologists of international repute and variously diagnosed as eczema, psoriasis, syphilis, and treated accordingly without result. The case then progressed to the tumor stage, and was referred by Dr. George Crary to the Cornell Cancer Research workers at the Memorial Hospital in January, 1914. The tumor formation was very extensive over the forehead, eyelids, cheeks, and back of the neck. Being so extensive various methods of treatment were applied over areas of the lesion, as follows: (1) Right forehead (most extensive tumor). excision and skin grafting; (2) left forehead, *x*-rays; (3) eyelids, desiccation, and (4) cheeks, radium. The results of the treatments showed (1) area excised and skin grafted, good results at first, later flap broke down in center and sloughed, exposing the skull; (2-4) in areas treated by the *x*-rays and radium the results were best and the cosmetic result was much better than where the surgical removal was attempted; (3) in the areas desiccated, the disease recurred; all of the lesions, however, disappeared within three months after the treatment was instituted. Two months later the patient returned with a generalized erythematous eruption all over his body. Inasmuch as their previous experience with this case had demonstrated the superiority of radium and *x*-ray treatment over all other methods, it was decided to treat the recurrent areas with radium and *x*-rays, using various filters in order to determine the best technique to employ in such cases. It was found that the *x*-ray technique was better; there were no subsequent irregularities of pigmentation in the skin treated; it was quicker; the larger areas of skin could be treated; the areas treated through a filter of 1 mm. of aluminum responded quicker and better than areas treated without filters or with thick filters. The patient's eruption entirely disappeared; there had been occasional relapses of the erythematous dermatoses since which always yielded to *x*-ray treatment.

Mycosis Fungoides; Case in the Pre-Tumor Stage.—Dr. J. FRANK FRASER (by invitation) presented this case. The patient was 70 years of age and came from a family of long-lived parents. He enjoyed good health until attacked by this disease. The first signs appeared six years ago, when he observed what he described as rough and scaling patches on the chest and back. About four months after these patches became red and itchy, but the itching did not become very annoying until about a year later. The patient presented himself at Dr. Trimble's Clinic at the University and Bellevue Medical College in August, 1913. The whole skin surface, with the exception of the hands, forearms, and face, was covered with variously sized erythemato-squamous patches. The color of the skin over the chest and abdomen was bright red, giving the patient the characteristic "Homme rouge" appearance. At the present time the lesions were of the type which the text books describe as belonging to the intermediary, secondary, or infiltrated stage. The diagnosis on clinical grounds was not difficult.

Dr. ISAAC LEVIN said that the results of the *x*-ray treatment of these tumors were quite striking. He said he would like to take exception to the remark that had been made that a patient was going ultimately to die of this disease; he had a patient with this condition whom he had been carrying along with *x*-ray treatment for five years.

Dr. GEORGE SEMKEN reported a case of mycosis fungoides that came under his observation five months ago, and the disease was rather advanced. This patient had been treated by the *x*-ray at the Skin and Cancer Hospital. For a time there was an initial improvement, but this had been followed by a recurrence that was worse than the original disease.

Dr. ARTHUR F. HOLDING said that these two cases illustrated well the pre-tumor and post-tumor stages of a very rare disease; in the pre-tumor stage usually seen by dermatologists and rarely correctly diagnosed until the post-tumor stage, when it was generally seen by surgeons, who should not operate on these tumors.

Septic Kidney Infarct from Infected Finger; Nephrectomy.—Dr. CLARENCE A. MCWILLIAMS presented this patient. He stated that she was 38 years of age and had been admitted to the Presbyterian Hospital Dispensary on June 3, 1916, with an abscess on the bolar surface of the left index finger occupying almost the whole of the anterior closed space. This was opened and made into a single cavity. Five days later freer drainage of the finger was afforded by lateral incisions. Sixteen days after this the terminal phalanx was found to be bare and necrosed. She was admited to the hospital one month after the beginning of the primary finger abscess, giving the history that for twelve days she had been feeling very ill, and had been having pain in the right side of the abdomen, which was sharp, situated in the right costal vertebral angle, and radiated down the course of the ureter. The pain was made worse by walking. The patient had chills, fever, and increased frequency of urination. Examination on admission showed a tender mass on the right side of the abdomen extending from the costal margin to the crest of the ilium, very tender in the costal vertebral angle. The *x*-ray showed no calculi in the kidney or ureter. Ureteral catheterization the following day showed clear urine coming from each kidney. Examination of the secretion from each kidney showed that the right kidney, probably from irritation, was doing a greater amount of work than the left. The urine from the right ureter showed 6.84 gm. of urea per litre and microscopically few pus cells and no casts. The secretion from the left ureter showed 6.396 grams of urea per liter, and microscopically few pus cells and no casts. The phthalein test showed 61 per cent. excreted in two hours the day before operation. There were no red cells in the bladder urine and no tubercle bacilli. At the time of admission the patient's white blood cells numbered 14,800, and polymorphonuclears 86 per cent. The temperature was 103° F., and pulse 102. The temperature remained remittent, the highest being 103° F. and the lowest 101° F. before operation. A diagnosis of perinephritic abscess was made because of the tenderness and the lack of evidence on catheterization of the ureters of any pus focus in the kidney. Four days after admission, July 7, 1916, the patient was operated upon. The kidney fatty capsule was very adherent, and on dissecting it three abscesses were opened. These were supposed to be in the kidney substance. Nephrectomy was done and drainage was provided. Culture of the pus showed the *Staphylococcus aureus*, the same organism which had caused the finger infection. A thick layer of fat adherent to the kidney was removed with the kidney. Two of the three abscesses were in this fatty capsule, while the third communicated with an embolic abscess in the kidney cortex. Two rubber drainage tubes containing gauze wicks were placed down the pedicle. For one month after the operation the patient ran a very puzzling and unexplained temperature. Physical examination and *x*-ray examination of the chest showed no complications there. It was six weeks before the sinus closed. Two months after the nephrectomy the whole necrosed

terminal phalanx of the index finger was removed, under local anesthesia, 2 per cent. novocaine. The patient had been well since leaving the hospital and had gained in weight. Micturition was normal and without discomfort. Examination of the urine showed it to be normal. The pathological examination showed a left kidney 14¼ x 8 x 5 cm. The cross section showed the capsule enormously thickened, including both the real and the fatty capsule. In places the two capsules measured 2 cm. in width. In the lateral aspect of the capsule was a good-sized abscess, the walls being very shaggy and containing broken down pus and blood. The cortex of the kidney showed a well-defined suppurative process about 2 cm. in diameter. In one case the cortex had been broken down and communicated with the perinephritic abscess. The kidney showed a thickened cortex and the capsule proper stripped off with difficulty; in the gross only one abscess was apparent. The mucosa of the calices and the pelvis of the kidney were markedly edematous and contained pus. The microscopical examination showed a suppurative nephritis. The glomeruli had been secondarily infected, as had the tubules themselves. There was marked edema and acute inflammation of the capsule and perinephritic fat.

Resection (Polya Operation) of Stomach for Cancer; Well after One and One-half Years.—Dr. CLARENCE A. MCWILLIAMS presented this patient. The patient was a man, 48 years of age, and had been admitted to the hospital August 18, 1915, eighteen months ago, complaining of cramps in the stomach for four months. The patient stated that sixteen years prior to this he began to have stomach trouble, vomiting about once a week, with no hematemesis, but with pain coming on from one-half to one hour after meals. The attacks were intermittent, there being an interval of several weeks between them. The attack previous to his present attack had occurred two and one-half years ago. Loss of appetite and weight were very pronounced, thirty pounds having been lost during the past four months. Examination showed a definite hard mass, moderately tender, and movable in all directions, in the left epigastrium. Inflation of the stomach caused the mass to disappear. A test meal gave 85 c.c. of moderately thick gray fluid with much mucus. The total acidity was 44 c.c., free hydrochloric acid 22 c.c. There was no lactic acid and no blood. The Wassermann reaction was negative. Blood examination showed 3,888,000 red cells, with hemoglobin 75 per cent. The *x*-ray examination was inconclusive. Operation was performed on August 20, 1915. An indurated mass was found occupying the middle of the lesser curvature in a saddle fashion, extending on both surfaces for an inch. The outer aspect looked like scar tissue. There were no adhesions along the lesser curvature. Extending over to the middle of the stomach were a small number of soft enlarged glands. Corresponding to the indurated area on the lesser curvature were a few small easily palpable glands. In view of the fact that it was impossible to tell whether the mass was an ulcer or a cancer, as well as the fact that the mass was situated in the middle of the stomach, in which position a gastroenterostomy would be of no use, and also the age of the patient—48 years—it was decided to do an excision. The gastrocolic omentum was ligated close to the transverse colon beyond all the enlarged glands, the two vessels at either end of the greater curvature being ligated separately. The lesser omentum was ligated off distal to all enlarged glands, the two vessels at the extremities being separately ligated. The duodenum was divided with the cautery between two clamps close to the pancreas, leaving just stump sufficient to invaginate. An over and over catgut stitch was put in beyond the clamp, and a purse string of Pagenstecher sutures buried the stump, whose end was then covered by suturing it to the pancreas. Two clamps were placed on the cardiac end as far proximally as possible; this enabled him to remove two-thirds of the stomach, the division being made with the cautery. The jejunum was then drawn up through an opening made in the transverse mesocolon and the side of the jejunum was sutured to the whole length of the opening in the stomach by a posterior serous continuous Cushing suture with Pagenstecher silk. There was no attempt made to narrow the opening in the stomach. The mucus surfaces were sutured with through and through continuous chromic sutures reinforced by several plain gut sutures. The opening in the mesocolon was sutured with plain catgut to the stomach and the intestine. The patient was in good condition after the operation, which lasted one hour and fifteen minutes. Convalescence was uninterrupted. Since the operation the patient had gained 25 pounds and had very little digestive disturbance, his only complaint being that he could not eat a square meal in amount; frequent small meals agreed with him better. The *x*-ray photograph taken a week ago showed an enormous dilatation of the remaining portion of the stomach. The pathological specimen consisted of the distal two-thirds of the stomach, measuring 14 x 6½ x 2½ cm. There was found on the lesser curvature the remains of an ulcer. There was marked indurated thickening of the lesser curvature, with some ulceration of its inner surface. On cross section, the mucosa and submucosa appeared considerably thickened. The pylorus was apparently normal. There were a few definitely palpable glands on the lesser curvature from which sections were taken. The microscopical examination showed a diffusely infiltrating carcinoma of the stomach. Section of the lymph glands removed showed in one corner the involvement of the lymph glands with the same type of tumor cells.

Dr. ISAAC LEVIN said that the case in which the regional lymph glands were affected was no longer an early case of cancer; Dr. McWilliams' case was not an early case, but already an advanced case. He had had an exactly similar case in every particular, and in which the operation was practically the same as in Dr. McWilliams' case. This patient was entirely well after two and one-half years. He then developed an acute cachexia, and showed a recurrence in the pancreas and liver. It might be possible that this patient would have a recurrence in the same area. They were not giving these patients a fair chance unless they gave them post-operative *x*-ray treatment. In order to make the *x*-ray treatment after operation more effective it was well to try as much as possible to bring the stump of the stomach as near the skin as possible, where the penetration by the *x*-ray was better. He had one patient who was still well after three and one-half years, who had been receiving the *x*-ray treatment. The patient might have remained well without the *x*-ray treatment, still he thought it was better to give the patient this additional chance.

Dr. HARRY E. ISAACS said it might be of interest in reference to the question as to whether an obstruction in the duodenum might have caused the dilatation of the stomach, to mention that he had a patient in whom a resection of two-thirds of the stomach was done for a sarcoma. The stomach was anastomosed from the cardiac end to the pyloric, and there was no point of obstruction, yet an *x*-ray recently taken showed a very large stomach.

Dislocation of the Carpal Semilunar.—Dr. CHARLES E. FARR presented two patients and gave a lantern slide demonstration showing various forms of dislocations of the carpal semilunar, alone and in combination with fractures of the scaphoid and of other structures in the vicinity. The first patient, a negro, had fallen a distance of 25 feet and received a number of injuries, among them this dislocation of the semilunar, which was not discovered at the time. After some months the man came under the speaker's care. The nature of the injury was then suspected by him, and confirmed by *x*-ray examination. As the dislocation could no longer be reduced, the semilunar was excised. Function had been almost completely restored, though the patient still complained that his wrist was somewhat weak. The second case was that of a man who had fallen in July, 1916, at which time attempts at reduction were unsuccessful. A few days later the patient came under Dr. Farr's care, and in this instance he had succeeded in effecting a partial closed reduction, which had been followed by nearly complete restoration of function. Dr. Farr said he had series of ten dislocations of the semilunar in nine individuals, nearly all of which had been overlooked until carefully studied by the *x*-ray. The points to be brought out were, first, that these injuries could not be very scarce since he had found this number in a comparatively short period of time. While they

were not common, they were certainly not uncommon. A second point brought out by the results in this series of cases was that the results of closed reduction were better than those of excision as regarded subsequent function. This fact made early diagnosis of importance since reduction could be more easily accomplished shortly after the injury than at a later period.

Treatment of Certain Fractures of the Tibia and Fibula.—Dr. FARR gave a lantern slide demonstration showing the character of the fractures and the results of treatment. One case was a compound fracture in which he could not reduce the fragments into position by any of the usual methods. The patient had a severe infection so that all that could be done for a time was to keep the wound as clean as possible. He later did a simple operation on the fibula, putting the two ends of the fracture into apposition, where they had remained. In the second instance the fracture of the tibia was of the compound, oblique, comminuted variety, and it was impracticable to operate upon the tibia. He therefore endeavored to see what could be accomplished by operating on the fibula. The ends of the fibula were drawn together, freshened, and simply approximated without internal fixation. The tension of the muscles helped to hold the ends in apposition. Though there was one-half inch shortening before the operation the shortening today was negligible in quantity.

Dr. WILLIAM DARRACH said he wished to emphasize two points in the diagnosis of anterior dislocation of the semilunar. First, that in these cases there was a marked increase in the antero-posterior diameter of the wrist, and secondly, that there were frequently associated symptoms due to the pressure of the displaced bone on the median, sometimes on ulnar nerve, as well as flexor tendons as they lay in the carpal canal. The nerve pain and immobility of the fingers, together with the increase in diameter, should make one suspect this condition. This lesion was considered by some French surgeons as a dorsal displacement of the os magnum, as in the milder displacements the semilunar maintained its normal relation to the radius. With the more marked rotation of the semilunar on the transverse axis, hinging on the intact anterior ligament, the os magnum resumed its position in the axis of the forearm, and under this condition the term "anterior dislocation of the semilunar" seemed more proper. The semilunar was not completely reduced unless its concave under surface could be seen in a lateral *x*-ray to have engaged over the head of the os magnum. Incomplete reduction would interfere with flexion and extension at the wrist as well as with the movements of the flexor tendons. When seen early many of these cases could be reduced by extreme hyperextension, traction, pressure over the displaced bone, followed by flexion. When the condition was not recognized until some time had elapsed, closed reduction might be impossible. Open reduction should then be attempted, and if a curved elevator could be made to engage proximal to the head of the os magnum, the semilunar could frequently be pried back into place. If reduction was impossible, the bone should be removed. As regards *x*-ray interpretation, the most significant factor of antero-posterior views was the loss of the clear space normally seen between the semilunar and the scaphoid, rather than the overlapping of the head of the os magnum by the lip of the semilunar.

Cicatricial Deformity of the Hand; Flap Transplantation.—Dr. GEORGE H. SEMKEN presented a patient, 24 years old, who had sustained a severe burn of the palm of the right hand during his infancy. As a consequence there was a considerable loss of tissue in the palm and along the palmar surface of the 2nd, 3rd, 4th and 5th fingers. Subsequently, contraction of the palmar fascia developed. When he came under observation his hand presented a well marked flexion deformity involving all the fingers. There was dense cicatricial tissue in the middle of the palm, extending thence across the bases of the fingers and upon their palmar surfaces. The 5th finger was fixed along its entire length. The thumb was drawn inward by firm fascial bands; the skin of the palm and wrist was hard and wrinkled like parchment. Function was fairly good in spite of the deformity, and there was evidently no tendon fixation in the scar. After describing the technique he followed in this instance Dr. Semken said that in the treatment of such defects it was not sufficient to cover the raw surfaces with Thiersch grafts because secondary contraction always occurred and reproduced the deformity. It was necessary, therefore, to replace the lost tissues with a flap of skin and subcutaneous fat tissue from some other part of the body, leaving it in vascular contact with its site by means of a pedicle until it had become firmly united to its new site in the hand. The flap in this instance was obtained from the lower part of the left axilla and the back, where the layer of subcutaneous fat was thin, and where the flap could contain the complete vascular system of the subcutaneous fat layer, as well as the skin. This flap, suitably shaped, was outlined with its apex posterior and its base or pedicle in front; it was then raised, turned back upon the anterior chest and provisionally wrapped in gauze moistened with saline solution. The defect in the chest wall was wholly closed by suture. The hand was brought over across the chest, and the flap was carefully sutured into place, with the apex of the flap at the wrist and the pedicle of the flap under the fingers. Healing was uneventful. The fingers had good function and extension was now nearly complete. The blood supply of the flap was excellent. Sensation had also returned and now seemed nearly normal.

Dr. JOHN DOUGLAS said he had performed an operation very similar to that of Dr. Semken, with the exception that he made the flap from the abdominal wall. The result in his case was a rather broad, flat palm, but at the same time it was a very good result and there was a return of sensation.

Dr. SEMKEN, in closing the discussion, said that in preparing these flaps, it was desirable to include the whole subcutaneous fat layer, so as to preserve the anastomosing vascular system uninjured. As thin flaps were needed for the hand, one must select a site on the surface of the body, where the subcutaneous fat layer was thin, so that it could be used *in toto*. That was why the lower axilla was chosen. Respiratory movements must be controlled as much as possible.

Fascia Transplantation into Lateral Defects of the Major Arteries.—Dr. HAROLD NEUHOF made this presentation, which he liberally illustrated with lantern slides. He stated that for the replacement of an arterial defect the implantation of a section of an artery had been, up to the present time, the best procedure. Implantation of a vein was less desirable because thrombosis and occlusion not infrequently supervened. Carrell had described an arterial patch as the best method for repairing lateral (sub-total) defects of arteries and more recently he had investigated the possibilities in the use of a patch consisting of peritoneum and adjacent musculature. He had demonstrated that a small lateral defect of an artery could be satisfactorily replaced by a transplant other than a vessel wall, but approximating arterial structure in the smooth peritoneal lining on one side and the attached muscle on the other. The author in the present communication demonstrated that fascia was as serviceable as vessel wall or peritoneum muscle for the replacement of even large lateral defects of the major arteries and at the same time offered greater possibilities for clinical application in the appropriate problems offered by human surgery. Except in the hands of a master of blood vessel surgery technique, the simple end to end suture of a divided vessel resulted in failure in almost 50 per cent of the experimental attempts. In patching an arterial defect with a section of artery or vein or peritoneum muscle, the same painstaking technique was required as that for an end to end suture of an artery, and the operation, being more complicated, an even higher percentage of failures could be expected. Theoretically, the writer believed that it was not necessary to employ morphologically similar tissues to adequately replace lateral arterial defects; he believed theoretically that a simple strong connective tissue (fascia) would offer several advantages, for it could be used without fear of damaging a delicate intima, without the necessity for accurate apposition of layers and without all the refinements of technique essential to the success of other transplants. It was evident that autotransplants of pieces of artery were not obtainable in human surgery and were therefore not to be considered. Vein grafts were more feasible, but to obtain them a separate wound exposure might be required and valuable time sacrificed for the careful dissection and proper preparation of the trans-

plant, and the necessary ligation of a large venous trunk was never desirable and by no means always harmless. The abdomen would not be opened merely to obtain peritoneum muscle transplants; their applicability would therefore be sharply limited to lateral defects of intra-abdominal vessels. Autotransplants of fascia (aponeurosis) were accessible in the neighborhood of almost every operation wound. Fascia lata was, however, because of its strength, smoothness, and even consistency, best suited for grafting. It was readily obtainable and its removal was harmless. The replacement of large defects in order to be feasible must be clinically applicable in the presence of incomplete hemostasis of the artery receiving it, for large defects of the smaller arteries, for the thoracic aorta where pressure was highest and prolonged obstruction of the arterial current was not possible, and the technique and armamentarium involved must be simple to the universally applicable. The results of the experiments which the writer reported showed that all these requirements were fulfilled by the use of fascia transplants. Seven experiments were performed, in four of which a sufficiently long period of time had elapsed (six to nine months) to report the more permanent results. In only one instance, fascia replacement of a large defect of the abdominal aorta, involving almost the entire circumference, did hemorrhage follow. The outcome was good practically but poor histologically in one femoral artery, thrombosis and cannulization having supervened. The results of all the other experiments were entirely satisfactory, anatomically, functionally and histologically. The technique of the operation was simple. Except for the addition of sterile vaseline, fine ordinary sewing silk and small calibered straight needles, no changes were made in the usual operating room asepsis and armamentarium of their animal laboratory. Ether by insufflation was used for the operation on the thoracic aorta, by the rebreathing method for the other experiments. The artery was exposed, the portion from which the piece was to be taken was isolated, its hemostasis was established by a rubber protected clamp at each end, and the ligation or temporary clamping of branches of the artery between them was effected. The desired section of the wall of the artery was then excised and the defect measured with a sterilized steel tape. Blood in the interior of the vessel was washed away and a gauze sponge freely spread with vaseline was placed over the exposed lumen. The fascia lata was then laid bare near the knee joint, a section of the desired shape and of slightly larger size was measured off, removed, dipped in vaseline and immediately placed over the arterial defect with its smoother surface facing the lumen. It was fixed in place by four sutures, and a continuous suture, approximating the edge of the fascia to the cut edges of the artery, was made between them. Compressing the patch lightly with a piece of vaselined gauze, the lower and then the upper clamp of the artery were removed. If there was oozing from gaps between individual stitches, reinforcing ones were passed.

Dr. Farr asked Dr. Neuhoff whether he had overlapped the fascia over the openings and what he thought the chances of success were in the presence of infection.

Dr. Douglas asked how long one could safely cut off the circulation and how long it took to perform the operation.

Dr. Neuhoff, in closing the discussion, said that if the defect of the artery were overlapped with fascia a certain proportion of the results would be satisfactory, but some would not. He believed the edge to edge suture throughout gave a much more inviting opportunity for overgrowth of mesothelium and most solid and resistant unions. Concerning infection, that was a question that must be faced in many attempts at surgery of the vessels in question. He had had no experience with surgery of the vessels in the presence of infection, but it might be interesting to call attention to the fact that he had had very satisfactory results in transplanting fascia into defects of the urinary bladder, the gastric wall, etc. He thought, therefore, that fascia transplantation into arterial defects might be attempted even in the presence of infection. As to the time that a vessel might be clamped off, experimentally the abdominal aorta might be occluded for an hour or an hour and a half. There was one clinical report of a resection of the aorta with end to end suture in which the vessels were obstructed for possibly a half-hour without deleterious effect. Concerning the question of thrombosis at blood vessel operations, this depended directly upon gross errors of technique and not upon the length of time that the arterial stream was shut off.

Bone Grafts in Ununited Fractures of the Long Bones.—Dr. John Moorhead presented this contribution. After reviewing the main sources of non-union, he stated that between one-half and one per cent of all fractures of the long bones failed to unite. Statistics usually credited the humerus as the most prone to non-union. His experience, however, gave the lower one-third of the tibia first place, the radius and ulna next, and then the femur. Clinically, a state of non-union might be stated to exist if the fragments were yet ununited after a period of 50 per cent. beyond the time usually allotted for union in that particular bone. The long bones knit in from four to eight weeks, and if union was unprogressive in a given bone after six to twelve weeks, the term non-union was justified. Delayed union did not always mean non-union, as in time some sort of union inevitably occurred. Operative procedures varied according to the individual, the type of the fracture and the findings on exposure of the parts. The bone graft was of great value, notably in that group of cases in which local reparative processes were at a discount. The graft should include the periosteum, the cortex, and some of the medulla. He had found that the width of the graft should be about one-third, and the length twice or thrice the diameter of the fracture site, and the thickness one-third the diameter. It should be anchored in place by kangaroo or chromic gut passed through holes bored at the edge of the channel that held it. The technique should be of the "hands off" variety, and the grade of asepsis should be superlative; a tourniquet should not be used. Active hemostasis was to be attained. Dr. Moorhead stated that experience had taught him to immobilize the grafted part 50 per cent. longer than the average period for splint wearing in an ungrafted fracture. Resumption of function was very guardedly permitted, and particular caution was taken to delay rotation in the forearm, and weight bearing in the lower extremities. During 1916 the writer had performed a bone grafting operation in 11 cases of non-union. Of these five were, for non-union of the tibia, three of the radius, and one each of the ulna, the neck of the femur, and a trephine defect of the frontal bone. Of these grafts, 77 per cent. were successful at the first operation. The elements contributing to success were: 1. The type of patient. The systemic condition of the patient should be as nearly up to par as possible. The local condition demanded a clean operative field; failure was invited if incision had to be made into an area of scarring, and notably if infection of the soft parts had previously occurred. 2. The type of fracture. The inlay two-piece graft taken from the fracture site was satisfactory if the selected bone was not too dense or too friable, and if on sectioning cut and looked like healthy bone. If, however, the contrary obtained, the unbroken tibia was the site of choice, and the incision over the skin should be so placed that the subsequent scar did not overlie the place from which the bone had been resected. It was important for the subsequent strength and contour of the leg that no portion of the crest be exsected. Dr. Moorhead reviewed the status of bone grafting in general and stated that at present it was the standard method of cure for non-union; but that the prevention of non-union would only come from the general recognition of the clinical fact that mal-union and non-union were invited, and certain bones inevitable if proper attention was not given to the dictum that adequate coaptation of separated edges was necessary to primary and perfect union in bones as in soft parts. It seemed probable that the time was at hand when the profession would realize that fracture surgery was major surgery, and that the place for a patient with a broken bone was in the hospital until the stage of convalescence was reached. Of all measures this would probably have the greatest effect in limiting non-union and other preventable complications.

Dr. William Darrach said that Dr. Moorhead had said much in a short space of time; his paper was one of the most concise that he had heard for some time.

As to the use of the term non-union, fifty per cent. additional time did not mean non-union but delayed union. Many cases would get union, but at a greatly delayed time; one sometimes had to wait six to nine months before getting solid union which would make operation unnecessary. A very simple procedure had been suggested to take the place of bone grafting, and that was Bier's method of injection of blood into the site of the fracture. This had been followed by solid union in so many cases that he had tried it two or three times in cases in which every other method had been tried before. It was surprising how much added strength was effected by this method; however, he had wondered whether it was the actual injection of the blood that produced the result, since so little of it really reached the site of the fracture, or whether it was the hemorrhage caused by the needle penetrating the tissues that was responsible for the favorable results. This was a method that should be employed before any radical operation was resorted to. Another element that might influence non-union was the slowing up in the reparative processes associated with prolonged immobilization. This was analogous to atrophy of bone as evidenced by the *x*-ray, seen in any case that had been immobilized for a long period of time. Massage and general active and passive motion tended to avoid or lessen this factor.

Dr. HENRY H. M. LYLE said that Dr. Moorhead had brought out the point that a very large percentage of delayed unions were the direct result of poor reductions or of poor immobilizations; close to 85 per cent. of non-unions were attributable to these causes. The most that he had seen were due to bad reductions in compound fractures. Practically all of these were treated without open operation. The Steinman pin or the stirrup or some form of traction must be used in these cases. Dr. Lyle stated that he had seen hundreds of these cases, and that if one was able to apply traction they could be cured. As to the stirrup, he had seen some bad results from the use of the stirrup in infected cases. In one instance it had cut into the tendo-Achilles and the muscle, and practically ruined the leg. The Steinman pin placed through the oscalcis could not do much harm even if there was some infection. As to the Beir method of injecting blood, he had been using that constantly, and he held off before doing a bone grafting operation longer than the ordinary worker did. The point of the whole matter was that about 85 per cent. of non-unions were the fault of the surgeon or of the medical profession, and not of the patient. An interesting thing about the Lane plate was that the statement had been made that it would soon be considered malpractice to put in a Lane plate.

Dr. JOHN GERSTER called attention to Lexer's studies of the local blood supply during the healing of fractures. These were published in the *Deutsche Zeitschrift für Chirurgie*. Lexer's findings had a direct bearing upon the technique of open operations. In a series of recently fractured limbs, at different periods the animals were killed and the main artery was injected with an emulsion of mercury and turpentine. The subsequent *x*-ray picture showed a congestion of the blood vessels of the soft parts adjacent to the fracture. This local engorgement reached its maximum at the end of three weeks, and then subsided in another week or so, as consolidation became established. The vessels in the bone close to the fracture line showed no such degree of congestion as that seen in the adjacent soft parts. In experiments where the periosteum was removed, the blood supply to the bony tissue was greatly reduced. Lexer stated that the main blood supply reached the bone through the periosteum, and therefore the greatest care should be taken to leave the relationship between soft parts and periosteum undisturbed. For this reason he made a long ample incision down to and through the periosteum, using a large knife so that all soft part layers were practically undisturbed. The periosteum (in undisturbed contact with the soft parts) was stripped from the bone for several inches above and below the site of fracture. According to Lexer, as long as this periosteum-soft part contact was intact, one need have no fear of non-union because of such extensive subperiosteal denudation of bone. As additional proof of this theory, Lexer cited the well-known fact that *x*-ray pictures taken after plating operations for fracture often showed much more callus on the side opposite to the plate; he interpreted this as follows: In the usual operation, the soft parts were first separated from the periosteum-covered bone (thus depriving the periosteum of its main blood supply); after this, the periosteum was divided, pushed aside, and the bone exposed. On the side of the bone opposite to the wound the operator could not reach the tissues except with much difficulty, hence the periosteum-soft part relationship was not disturbed, and the subsequent nutrition and repair were much less hindered, Lexer was a staunch advocate of bone grafting for malunions and was opposed to plating operations. He cut down the cast at the end of three weeks and began passive motion, leaving a posterior splint for support.

Dr. WILLIAM LUCKETT said that Dr. Moorhead had spoken of syphilis as having been given as a cause of non-union, but that he had not found it a factor in non-union. He agreed with Dr. Moorhead on this point. In his experience he had found that the bones of syphilitics healed as promptly as those of other individuals. He had had two cases of locomotor ataxia in whom broken bones healed promptly; in one of these the man fell four times within three years, and union took place each time. He had another man, a prize fighter with syphilis, who fractured his radius, and it healed up quickly. He felt quite sure that syphilis had nothing to do with the non-union of bone.

Dr. L. M. KAHN emphasized what Dr. Lyle had said with reference to the use of the Steinman pin, that by drawing it through the os calcis and applying traction, remarkably good results could be obtained, especially in cases of compound and comminuted fracture. He would like to recommend it to his hearers.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL COUNCIL OF CANADA.

Montreal, October 10, 11 *and* 12, 1916.

(*Continued from page* 134.)

HYGIENE AND PUBLIC HEALTH.

1. Define (*a*) Terminal disinfection; concurrent disinfection; (*b*) Which is the more important, and why? (*c*) Describe in outline one good method for each; (*d*) In what diseases have (i) terminal disinfection, (ii) concurrent disinfection, been proved of value in reducing their spread?

2. (*a*) Describe clearly the different methods through which insects transmit disease, with a specific example of each method; (*b*) Suggest the best method to get rid of (i) flies, and (ii) malaria mosquitoes.

3. (*a*) Define the term "carrier"; (*b*) Mention those diseases which are spread by carriers; (*c*) Describe proper measures for control of carriers.

4. In case of impure water not corrected by municipal authorities describe different household measures which may be taken to successfully purify the water for consumption.

5. State what you know of the cause, mode of transmission, and means of prevention of the following diseases: whooping cough, diphtheria, typhoid, typhus fever, tetanus, acute anterior poliomyelitis, ophthalmia neonatorum, smallpox.

6. (*a*) What ill effects may be produced by (i) cold, (ii) heat? (*b*) What preventive measures may be used against them? (*c*) What ill effects may be produced by dampness in a house? (*d*) What measures may be used to prevent such dampness?

OBSTETRICS AND GYNECOLOGY.

1. Abortion: (*a*) Define the terms "threatened," "inevitable" "complete" and "incomplete" abortion; (*b*) Describe briefly how you would deal with each of these conditions.

2. What symptoms would lead you to suspect ectopic gestation? How would you diagnose the condition?

3. Forceps in occipotoposterior position of the head: Describe application and extraction.

4. What are the indications and the means of inducing labor and immediate delivery?

5. Fibroids of the uterus: Classify as to localization and give the symptoms of each class.

6. Discuss the causes and treatment of dysmenorrhea in the virgin.

ANSWERS.

HYGIENE AND PUBLIC HEALTH.

1. By *terminal* disinfection is meant the disinfection of a sick room and its contents at the termination of a disease. By *concurrent* disinfection is meant the disinfection of discharges, and all infective matter all through the course of a disease. Concurrent disinfection is by far the more important of the two, and the more thoroughly this method is carried out the less need there is for terminal disinfection. In diseases like typhoid, scarlet fever, and tuberculosis, concurrent disinfection should be insisted upon, and also a terminal disinfection. The latter may not always be necessary in a disease like measles. Both methods have reduced the spread of communicable diseases. Formaldehyde, in the presence of heat and moisture, is a good general terminal disinfectant. The *formalin-permanganate* method is in common use. 500 c.c. of formalin and 250 grams of potassium permanganate are required for each 1,000 cubic feet of air space. The permanganate is placed in a pail with a wide top, the formalin is poured on to the permanganate, and effervescence results with production of heat. The pail should be placed on a brick or other object to protect the floor from the heat evolved. In *concurrent disinfection*, different materials require different disinfectants; but in a general way chlorinated lime is a good disinfectant for stools; carbolic acid for sputum; superheated steam for linen.

2. *Insects* may carry disease by contact and by infecting food; typhoid and tuberculosis may thus be conveyed. Suctorial insects may also transfer infective material from the sick to the well; thus typhus fever may be spread by lice, and bubonic plague by fleas from the rat. Certain mosquitos may also act as intermediary hosts for pathogenic protozoa; malaria and yellow fever may be conveyed in this way.

To get rid of flies. Accumulations of dirt and filth must be removed or rendered distasteful to flies or larvæ by the use of lime, kerosene or cresol. Screens are used to keep flies out of houses; garbage must be disposed of in a proper manner; fly poisons such as arsenic or corrosive sublimate may be employed; fly traps are also useful; so, too, are fly papers.

To get rid of malarial mosquitos. All pools, stagnant water, or places where the anopheles may breed should be removed. Mosquitos and larvæ must be destroyed as far as possible. Fumigation by means of sulphur or pyrethrum will kill or stupefy the mosquitos, and in the latter case they can be swept up and burnt.

3. A *carrier* is a person who harbors a pathogenic microorganism but who shows no sign or symptom of the disease. The *following diseases may be spread by carriers:* Diphtheria, infantile paralysis, malaria, meningitis, tetanus, typhoid, cholera, pneumonia, influenza, cholera.

The *control of carriers* is extremely difficult. Sanitary isolation may be enforced, and the carrier must be made to exercise scrupulous and intelligent cleanliness, and must not be allowed to handle food intended for others. A "carrier" may be safely employed as a carpenter, seamstress, or in some similar occupation without danger to his fellows. In certain diseases, where it is possible, autogenous vaccines may be of service. In cases where treatment is unsuccessful or impossible the carriers should be under the supervision of the health authorities.

4. "Domestic water supply may be purified by sedimentation, boiling, distillation, chemicals, or by filtration. By *sedimentation* it is possible to free the water from its mechanical impurities, sand, dirt, etc., without, however, much affecting matters held in solution. By *boiling*, all organic matter and germs are destroyed; the taste of the water is, however, changed, owing to expulsion of gases. By *distillation*, a chemically pure water is gained, which may be made palatable by the addition of carbonic acid. By the *addition of chemicals* to suspicious water—small doses of borax, boracic acid, potassium permanganate, copper sulphate, etc.—the organic matter may be rendered harmless; but as those chemicals are not a desirable addition to water, this method of purification is objectionable. In ordinary households the boiling of waters is a good precaution whenever the water supply is suspicious. Distillation, provided the proper apparatus is at hand, is the ideal method. Water may be purified of all, or nearly all, of its impurities by filtration, the value of the process depending upon the medium of filtering, the efficiency of the filter, and the thoroughness of the process. The materials used for filters are wool, asbestos, sand, stone, porcelain, infusorial earth, carbide of iron, charcoal, etc. Infusorial earth pressed in the form of hollow tubes is used in the Berkefeld filters, which are efficient, although needing frequent cleansing."—(Price's *Epitome of Hygiene.*)

5. *Whooping cough* is caused by the bacillus of Bordet and Gengou. It is transmitted by the secretions of the nose and mouth, droplet infection, by the use of handkerchiefs, cups, toys, etc., also by domestic animals. Prevention is effected by fourteen days isolation of those who have been exposed to infection; the patient must avoid contact with others; isolation and avoidance of infection are necessary. Vaccines have been used.

Diphtheria is caused by the *Bacillus diphtheriæ.* It enters the body by the mouth or nose (occasionally elsewhere), and is conveyed by contact, coughing, speaking, fingers, toys, food, droplet infection, and by carriers. It may be prevented by isolation of cases and carriers, by the injection of diphtheria antitoxin, disinfection of mouth and nose discharges and of toys, cups, spoons, etc., used by the patient.

Typhoid is caused by the *Bacillus typhosus.* It enters the body by the mouth, and is conveyed by food, fingers, flies, carriers, and fomites. It may be prevented by inoculations; early diagnosis and isolation, with proper disinfection of secretions are necessary; proper water supply, and suppression of flies are important factors in the prevention of this disease.

Typhus is caused by an anerobic bacillus, described by Plotz. It is transmitted by the body louse. It may be prevented by cleanliness of person and clothing, destruction of lice and nits; the patient's hair must be clipped, and his clothing baked or steamed.

Tetanus is caused by the tetanus bacillus. It is spread by soil, dust, flies, and is a wound complication. Prevention consists of cleanliness, avoidance of wounds, free opening of punctured and lacerated wounds with removal of foreign matter. Excision of the wound may be advisable; tetanus antitoxin is a specific.

Acute anterior poliomyelitis is caused by a filterable, "ultramicroscopic" virus. It is transmitted by contact, the virus leaving by the discharges of the nose and mouth of one person and entering by the same route in another; insects are also believed to transmit the disease. Prevention is uncertain; isolation, cleanliness, and destruction of insects may all be tried.

Ophthalmia neonatorum. It is caused by the gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. Prevention: Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth.

Smallpox. The cause is unknown; so, too, is the mode of transmission. Prevention consists in vaccination, and prompt isolation of patient.

6. *Cold may produce the following ill effects*: Sense of chilliness, paleness of the skin, shivering, numbness, livid spots on skin, syncope, lassitude, languor, confusion of senses, dulness of mind, slow or interrupted respiration, small pulse, feeble and quick or irregular heart-beat, coma, and death. Tissue metamorphosis is rapid; more food (especially carbonaceous food) is required; oxygenation of blood and elimination of carbon dioxide are increased; skin functions are reduced to a minimum, and excretion of urine is increased.

Heat may produce the following ill effects: Respira-

tions are lessened, elimination of water and CO_2 is diminished, the heart's action is slowed, the appetite and digestion are impaired, the nervous system is depressed, the action of the kidneys is increased and that of the lungs is diminished, less food is required, metabolism is decreased, less urea is eliminated. *Preventive measures* include the avoidance of too sudden change from heat to cold, the protection of the body from cold and draughts, the wearing of proper clothing, and the protection of the extremities from cold. Attention must be paid to the skin and the urine, a proper amount of water must be drunk, alcohol should be avoided, and food must be suitable in quality and quantity.

Probable effects of dampness: "Damp houses are cold houses, damp walls are cold walls, because damp walls and moist air are good conductors of heat. Individuals lose more body heat in damp houses; more fuel is needed to warm such houses. Damp houses favor chilling of the body surfaces, have a depressing effect on the human organism, and decrease its resisting powers. Damp houses favor development of moulds, fungi, dry rot in wood, efflorescence and saltpetering in masonry, and also favor insects and germ life within the house. Damp houses cause the mildewing of clothes, injure furniture, produce spots on walls, make house cleaning difficult, heating expensive, interfere with ventilation, and decrease the suitability of the house as to comfort and shelter. Damp houses may safely be regarded as predisposing causes of tuberculosis, bronchitis, pneumonia, nephritis, rheumatism, and other diseases."—(Price's *Epitome of Hygiene.*)

To prevent dampness: "Perfect dryness of foundation, walls, and roof, and exclusion of ground air, are necessary conditions of house construction. The subsoil around the site, and, if there is much damp, also below it, should be drained, and, except where there is a rock foundation, the walls should be embedded in concrete, and under the whole house should be a layer of concrete 6 inches thick, having on the top a layer 1 inch thick of some impervious material, such as asphalt or cement. In order to prevent damp rising from the ground a *damp-proof course* should be inserted in the wall just above the ground level. Perforated slabs of glazed stoneware may be made to serve not only as a damp-proof course, but to ventilate the space under the floor. It is advisable to have a damp-proof course also where the rain-gutter joins the parapet, and in chimney-stacks just above the roof. Basement walls are liable to become wet when in contact with a damp soil even when there are drains and damp-proof courses. In this case 'a dry area' must be formed by digging out or by building a second thin wall outside and a few inches away from the main wall, or by inserting slabs in a slanting position between the soil and the house wall, or the walls may be built hollow (with two damp courses) and joined together with iron ties or bonding bricks, or the hollow may be filled with asphalt. Walls exposed to driving rain or sea spray may be coated with slates, vitrified slabs, alkaline silicates, or cement; but such coating should continue down to the 'footings,' and should not be applied while the bricks are wet. The walls of a newly built house are damp from the water used in mixing the mortar, and also that absorbed by the bricks. If salt water, sea sand, or refuse lime from soap works, containing glycerin, has been used in the mortar, it will never dry. Mortar should be composed of good lime combined with clean sharp sand, free from earthy matter (road scrapings or mold have sometimes been used by unscrupulous builders), or with crushed stone, slag, or well-burnt clay. Walls are sometimes built of concrete made with cement. For internal walls, where space is limited, coke-breeze with cement has been used. The settling of the walls sometimes breaks the drain passing underneath, if not properly protected by concrete or by the formation of an arched opening in the wall. It is usual to defer putting in drains until after the building has been carried up, with the view of allowing it to settle upon its foundations. If there be no cellars the flooring ought to be raised two feet above the ground, which should be covered with cement and the space ventilated to prevent growth of the fungus of 'dry rot.' Walls and ceilings are usually covered with plaster, which should be of good materials ('jerry' builders have been known to use a mixture of lime and sifted mold or street refuse for this purpose). It should be finished with a smooth, non-porous surface. If a room is not to be papered the walls should be coated with some form of cement or distemper, which sets hard and prevents percolation. In cheaply built modern houses the inner walls are often not carried up in brick beyond the first floor, and above this height are continued by a frame of wood filled in with lath and plaster."—(*Aids to Sanitary Science.*)

OBSTETRICS AND GYNECOLOGY.

1. In *threatened abortion* there are slight pains or hemorrhage which indicate that the uterus may empty itself, but there is a fair prospect that this may be prevented.

An abortion is *inevitable* when the signs and symptoms indicate that there is no method of preventing the uterus from emptying itself.

A *complete abortion* is one in which both the ovum and its membranes are cast off intact.

An *incomplete abortion* is one in which part of the ovum or membranes is retained in the uterus.

In *threatened abortion* the woman should be put to bed and her rectum should be emptied by an enema, a suppository containing morphine may be administered; if the hemorrhage is more than moderate in amount a vaginal tampon of sterile or iodoform gauze may be indicated.

Inevitable abortion demands rest in bed, and tamponade of the cervix and vagina; after the cervix is dilated the ovum must be removed and the uterus thoroughly cleaned out. Aseptic technique is necessary, and trauma and lacerations must be avoided.

In *incomplete abortion* the cervix must be dilated (if necessary), the uterus thoroughly cleaned out, and an intrauterine douche of sterile water given, a light tampon of iodoform gauze is placed in the vagina; a strip of gauze may be placed in the uterus in case of sharp retroflexion to secure free drainage, and sometimes an intrauterine tampon will be necessary when the hemorrhage persists or the uterus refuses to contract.

2. ECTOPIC GESTATION. *Diagnosis:* "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*"—(*American Text Book of Obstetrics.*)

3. *Forceps in occipito-posterior positions:* "The blades are put in exactly as for cases where the occiput has rotated anteriorly. But since the occiput is now toward the sacrum, the *extension will, of course, be downward and backward over the perineum,* instead of upward toward the pubes; hence the handles of the instrument, at first lifted somewhat upward toward the pubes to draw the occiput up to the edge of the perineum, must, when the head emerges, be directed *downward and backward,* instead of toward the *mons veneris.* A moment's reflection will show that the short *straight* forceps (without any sacral curve) should be used in these cases; for the said curve is only adapted to follow the axis of the pelvic canal, but during *backward* extension of the occiput over the perineum the head departs from the axial line and goes in an almost opposite direction. If the *curved* forceps were used, the ends of the blades would impinge against the pubic

arch while the handles were being depressed in following the movement of backward extension. Again, owing to the depth of the posterior pelvic wall being three times as great as that of the anterior one, there is so much the more difficulty in getting the occipital end of the occipitomental diameter to escape over the edge of the perineum, hence greater danger of laceration, and necessity for extra care that the occipital pole *really* shall have cleared the perineum before extension is attempted."—(King's *Obstetrics.*)

4. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head. The methods that may be employed are: Partial dilatation of the cervix and the introduction within the cervix (and vagina) of a tamponade of sterile gauze; (2) dilatation of the cervix; (3) puncturing the membranes; (4) introduction of a soft rubber bougie into the uterus; (5) intrauterine injection of glycerin, water, or some other fluid.

5. *Fibroids are classified* as: (1) *Interstitial* or *intramural*, when they are entirely in the muscular wall of the uterus; (2) *Subperitoneal* or *subserous*, when they bulge ontward beneath the peritoneum; (3) *Submucous*, when they bulge into the uterine cavity.

The *symptoms* are: (1) *Hemorrhage*, the degree of which depends upon the nearness of the tumor to the endometrium or to the peritoneum; the nearer to the uterine mucosa, the greater the hemorrhage, and the nearer the tumor is to the peritoneum, the less the hemorrhage. There is no relation between the degree of hemorrhage and the size of the tumor. (2) *Pressure* and *traction* may cause disturbances of rectum, bladder, ureters, urethra, and uterus; hence there may be tenesmus, diarrhea, frequency of urination, dysuria, retention of urine, uterine displacements, hydronephrosis, and cystitis. Other symptoms are pain, leucorrhea, anemia, and generally impaired health.

6. *Causes of dysmenorrhea:* Pelvic congestion, pelvic inflammation, malnutrition, overwork, lack of development, neuralgia, stenosis or obstruction of the cervix, prolapse or displacement of the uterus.

Treatment should first of all be directed toward discovering the cause and (if possible) removing it. General methods of treatment and hygiene are indicated; advice should be given on such matters as rest, exercise, proper diet, care of bowels and bladder, bathing, clothing, change of residence; massage, douches, tampons, and electricity may prove of service. Innumerable drugs have been recommended, such as apiol, bromides, phenacetin, antipyrin, cannabis indica, viburnum prunifolium, amyl nitrite, and salicylates. Alcohol should be avoided, if possible; so, too, should unnecessary local examinations and applications.

(*To be concluded.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ACUTE POLIOMYELITIS (INFANTILE PARALYSIS). By GEORGE DRAPER, M.D., with a foreword by SIMON FLEXNER. 19 illustrations, 149 pages. Published by P. Blakiston's Son & Co., Philadelphia, Pa. Price, $1.50 net.

THE MICROSCOPE. An introduction to microscopic methods and to histology. By SIMON HENRY GAGE. Twelfth edition, rewritten and illustrated by over 250 text-figures. 472 pages. Price, 3.00 net. Published by The Comstock Publishing Company, Cornell Heights, Ithaca, N. Y.

DISEASES IN MILK. THE REMEDY—PASTEURIZATION. THE LIFE WORK OF NATHAN STRAUS. By LENA GUTHERZ STRAUS. Second edition, revised and enlarged, to commemorate the twenty-fifth anniversary of the inception of the work. Published by E. P. Dutton & Co., New York City. Price, $2.50 net.

Therapeutic Hints.

Hemoptysis.—Excessive hemoptysis, not amenable to simpler remedies, may be stopped by the following:

℞ Ergotin .....
Acidi gallici.....āā gr. xv
Syr. althæ.....
Aquæ destill.....āā ℥vj

M. S.—A teaspoonful every two hours, p. r. n.

Urticaria in Children.—First remove the offending cause, whether external or dietary, more frequently the latter. Locally, baths containing bicarbonate of soda, also salines to clear out the intestinal tract, and local applications of ointments containing menthol, camphor, or carbolic acid. Small doses of salicylate of sodium or aspirin will relieve the intestinal fermentation.—*Diseases of Children*, Chapin and Pisek.

Acute Nasal Catarrh.—Sajous has found the following to act efficiently in the beginning of this condition:

℞ Ammonii chloridi.....gr. xl 2.6 gm.
Tr. opii.....m. xxx 2.0 c.c.
Sacch. albi.....℥ j 4.0 gm.
Aquæ camphoræ.....f℥ j 30.0 c.c.

M. S.—One teaspoonful in water every hour or two.—*Hughes' Practice of Medicine.*

Neuralgia.—This condition produced by exposure to cold and wet may be relieved by the following:

℞ Phenacetin .....
Salophen .....āā ℥jss (6.0)
Codeinæ .....gr. iij (0.2)

Fiant chartulæ No. xii.

S.—One powder every two or three hours.—*Stevens' Modern Materia Medica and Therapeutics.*

Epistaxis.—Harold Hays offers the following means for relief when hemorrhage from the nose occurs: The first thing to guard against is the demoralizing effect on the patient of the continuous bleeding. Careful watch of the pulse should be kept and patient assured that there is no danger of bleeding to death. In many instances, a dose of morphine will quiet the heart action and sometimes cure the hemorrhage, while fainting accomplishes the same result. If the condition cannot be attacked directly packing must be resorted to; anterior packing through the nostril, preferably with strips of bismuth subnitrate gauze may be all that is required. If more is needed posterior plugging is done by making a hard plug of gauze to fit one posterior naris, to which is tied a long piece of string, leaving two long ends; then a baby catheter is inserted through the affected nostril and out through the posterior nares, to which is tied one end of the string with the plug fitted into position. Such a plug should never be left in position longer than twenty-four hours, as an inflammation of the Eustachian tube and middle ear may result from irritation of the nasopharynx. Styptics, such as iron, alum, trichloracetic acid, suprarenalin powder, etc., may act and again they sometimes fail. Fifteen grains of calcium lactate or hypodermic injections of emetine or the extract of pituitary gland usually relieve this condition. Large doses of serum have been resorted to, and also transfusion.—*Medical Times.*

NEUROTIZATION OF PARALYZED MUSCLES BY IMPLANTATION OF MOTOR NERVES.

BY JOHN C. A. GERSTER, M.D.,

AND

W. C. CUNNINGHAM, M.D.,

NEW YORK.

(From the Surgical Laboratories, Department of Surgery, College of Physicians and Surgeons, Columbia University.)

IN 1906 Gersuny[1] noticed that incidental to the removal of a tumor of the face, a muscle which had been severed from its connection with the facial supply on that side, if replaced so that it lay in contact with the normally innervated muscles (from the facial) of the same or opposite side of the face, would ultimately regain its function. The case on which he based this theory was one of facial paralysis in which he dissected the orbicularis oris free and brought the sound portion of it past the midline, suturing it in this position. There was an ultimate return of function in the muscle.

Another case of his was a paralysis of the deltoid of unknown origin. Here he freed the deltoid and trapezius from their attachments to the acromion and scapular spine, and then brought up the paralyzed deltoid under the healthy trapezius and sutured it there. The arm was fixed horizontally. In 50 days the deltoid began to show return of function. Stimulation of the spinal accessory caused contraction of the trapezius, but stimulation of the circumflex evoked no contraction of the deltoid. Frankl-Hochwart at the time pointed out that this was no proof of non-function of the nerve—it is well known that voluntary contraction often returns before response to electrical stimulation.

In 1908 von Hacker divided the spinal accessory incidentally to extirpation of tuberculous cervical lymph nodes. There was a paralysis of the trapezius. Some time later (he does not state exactly) he implanted the central end of the cut nerve into the trapezius higher up, the peripheral end was implanted into the brachial plexus lower down, and, lastly, a flap from the levator scapulæ was implanted in the center of the trapezius. Apparently recovery was slow, for, at a second operation, the deltoid was

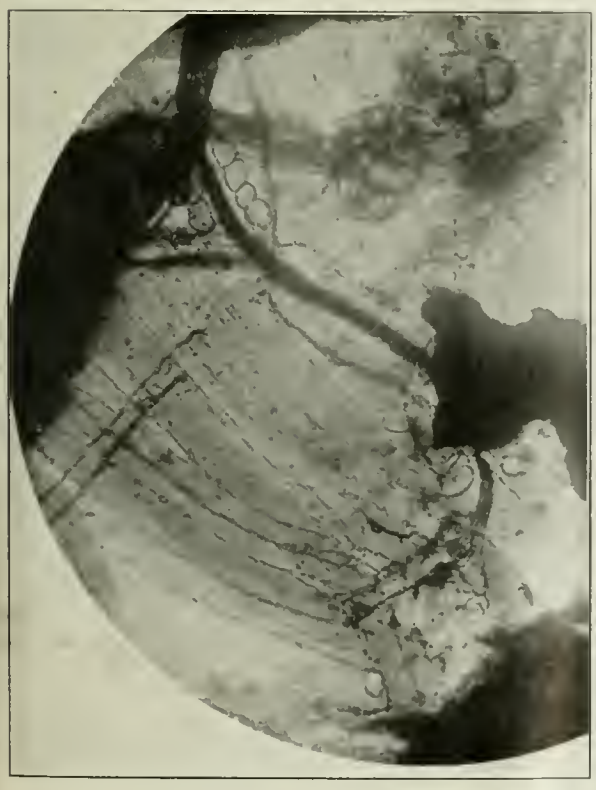

FIG. 1.

FIG. 2.

freed and implanted into a freshened cross section of the trapezius. Two years later there was complete restoration of function.

In a second case, von Hacker performed neurolysis for a deltoid paralysis of three months' standing. There was no result six weeks later; he then freed a flap of healthy trapezius and brought it into contact with the deltoid fibers. Six weeks later there was a return of function—the anterior fibers of the deltoid reacted to electrical stimulation. None of the cases just described are conclusive.

In 1914 Heinecke[2] of Leipzig reported having cut the posterior tibial nerve in rabbits and then having implanted the peroneal into the paralyzed gastrocnemius. In 14 days function began to return and in 8 weeks there was complete restoration. Implantation as late as 21 days after paralysis was successful.

Fig. 3.

Shortly after, Erlacher[3] of Graz reported having been at work on this problem since 1911. In a monkey the musculocutaneous had been severed and then reimplanted at another point into the biceps. There was return of function. Many other experiments (34 in all) were made on guinea pigs, using the biceps. As a result of these he claimed it was also possible to innervate (hyperneurotize) normal muscle with additional nerve trunks (by implantation), and lastly, to innervate paralyzed muscles by bringing their fibers intimately in contact with non-paralyzed muscular tissue.

Steindler[4] of Iowa City, in 1915, reported positive findings in 5 dogs. The anterior crural was resected and the sciatic was cut across low down, it was then implanted into the paralyzed quadriceps. After 10 weeks there was some return of function and after 16 weeks restoration was complete. He also reported innervation of paralyzed muscle in 3 cases of residual deformity following poliomyelitis (pes calcaneus with fair or good function of the long flexors of the toes). The posterior tibial was isolated and split; part of it was then implanted into the gastrocnemius by suture. There was return of function within 4 to 6 weeks.

In a later communication (1916) Steindler[5] recounted a second experimental series of 5 dogs and 2 cats in which the artificially paralyzed quadriceps was innervated by implantation of the cut anterior tibial.

In a recent number of *Science*, Elsberg[6] gives his experimental experience in this field. He states that it is possible to innervate a muscle after it is artificially paralyzed. It is not possible to hyperinnervate a normal muscle supplied by its proper motor nerve.

Since February, 1916, the author, with the assistance of W. C. Cunningham, has been conducting experiments on innervation (neurotization) of muscles along the lines described above. The gluteal hamstring group of muscles was deprived of its motor nerve supply. The anterior tibial nerve was divided close to the knee and then implanted into the paralyzed muscle belly. Owing to an epidemic among the operated rabbits, only 3 out of 13 furnished any positive findings. In fact, it was not until February, 1917, that a rabbit was obtained in which stimulation of the implanted nerve trunk evoked a normal strong contraction in the previously paralyzed muscle; this response was as strong as that obtained from stimulation of normally connected motor nerve trunks in the vicinity. This finding was repeated and confirmed at the end of May, 1917, the animal was killed and the muscle in the vicinity of the implanted nerve was examined for the author by Dr. J. H. Globus, who used the gold chloride precipitation method. The appended figures (1, 2 and 3), show branchings of the implanted nerve as well as motor nerve endings. Similar findings were subsequently obtained in two other animals. One showed a weak but definite response* at the end of 4 weeks, and a normal, strong response at the end of 12 weeks. The other showed a definite response at the end of 12 weeks.

From the foregoing experimental work of others as well as the author's—in which the same procedure has been applied to different groups of muscles in different species of animals with the same result—it seems fairly well proven that a recently paralyzed muscle can be innervated by implantation of a motor nerve. This may be the identical nerve which originally supplied the paralyzed muscle *or some other motor nerve.*

*Only the fibers immediately adjacent to the implanted nerve end contracted. At a subsequent examination 8 weeks later, the entire muscle contracted—seeming to indicate that innervation had spread peripherally from the site of implantation.

ETIOLOGY AND TREATMENT OF HEMORRHOIDS;

By J RAWSON PENNINGTON, M.D., F.A.C.S.,

CHICAGO

In a preliminary report to the American Proctological Society at the Detroit meeting (June, 1916) on "Anatomic and Bacteriologic Findings of the Ano-Rectal Region," the writer called attention to the sinuses and diverticula in this region. It was announced that cocci and other forms of bacteria had been found in their walls and contents, and the possible relations to focal infections, etc., were pointed out. The object of the present communication is to emphasize the connection between these sinuses and diverticula and hemorrhoids.

Fig. 1.—Photomicrograph of cross-section of the rectum just proximal to the pectinate line, showing many sinuses and blood vessels have been cut across.

Fig. 2.—Photomicrograph which shows beginning of a rectal sinus in a fetus six months *in utero*.

The principal causes of hemorrhoids are predisposing (embryological and mechanical) and exciting (bacterial). The *embryological* are the sinuses and diverticula just referred to. They were first noticed by the writer many years ago, when investigating the structure of the rectal valves, and were referred to in a paper published at that time[2] as "epithelial glands." He then frequently noticed the apertures of the sinuses and diverticula during the course of various operations on the lower bowel, and pointed them out to his classes from time to time. Not long ago, in a patient with hemorrhoids, one aperture was so prominent that a probe was inserted into the lumen for quite a little distance. This aroused renewed interest in the subject, specimens were collected, and investigations commenced from a bacteriologic standpoint.

Fig. 3.—Photomicrograph of a rectal sinus in a still-born child at full term. This sinus passes through the mucosa and sub-mucosa down to the circular muscular fibers.

Fig. 4.—Photomicrograph showing round-celled infiltration and infection in a rectal sinus

On looking up the literature it was a great surprise to find that these sinuses and diverticula had been described by Hermann and Desfosses[3] nearly forty years ago. Yet they are ignored in all text-

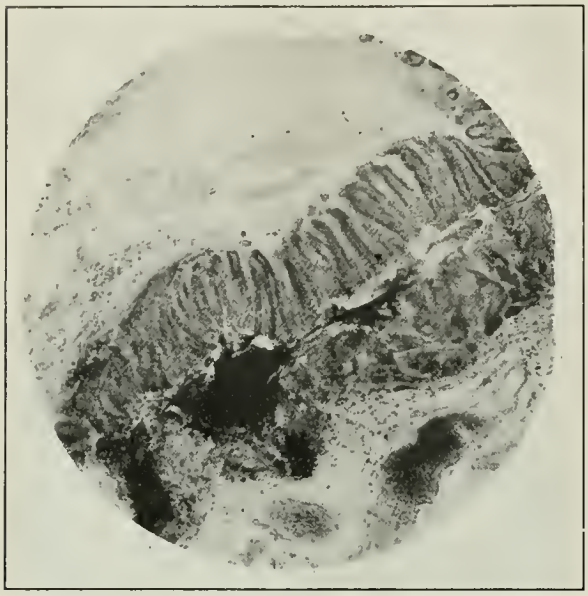

Fig. 5.—Photomicrograph of an infected rectal sinus in a hemorrhoidal specimen. The mucous membrane lining the sinus is broken down and numerous bacteria are seen in the sinus and surrounding tissues, as shown in Fig. 6.

books on diseases of the rectum and those on medicine and surgery. The only reference found of late years is in a paper on the anatomy, by Johnson[4].

It is not clear why they have been ignored unless it is that they have had no pathological possibilities

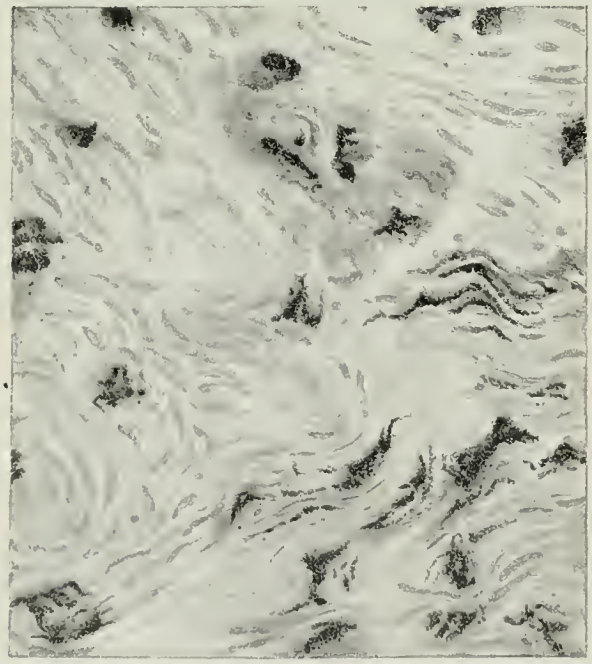

Fig. 6.—Photomicrographic sketch of a field in Fig. 5. It shows the microorganisms in the surrounding tissues in many places.

attributed to them. Yet, as will be seen both by referring to Figs. 1-6, and by actual clinical experience, they can be shown to be an exceedingly important factor in pathological processes in the rectum itself, primarily; and in exciting constitutional conditions, secondarily.

That an important anatomical fact should, in this scientific age, be disregarded or lost sight of for many years, after being placed on record, and then, without knowledge of its former discovery, be rediscovered and found to be of great importance as a disease-producing factor, is almost unbelievable. However, this anatomical finding when resurrected proves to be of a vital etiological factor in the causation of hemorrhoids and other diseases of the rectum with their metastatic sequelæ.

The *mechanical* causes are those conditions interfering with the return flow of blood; these slow the blood current and produce dilatation of the

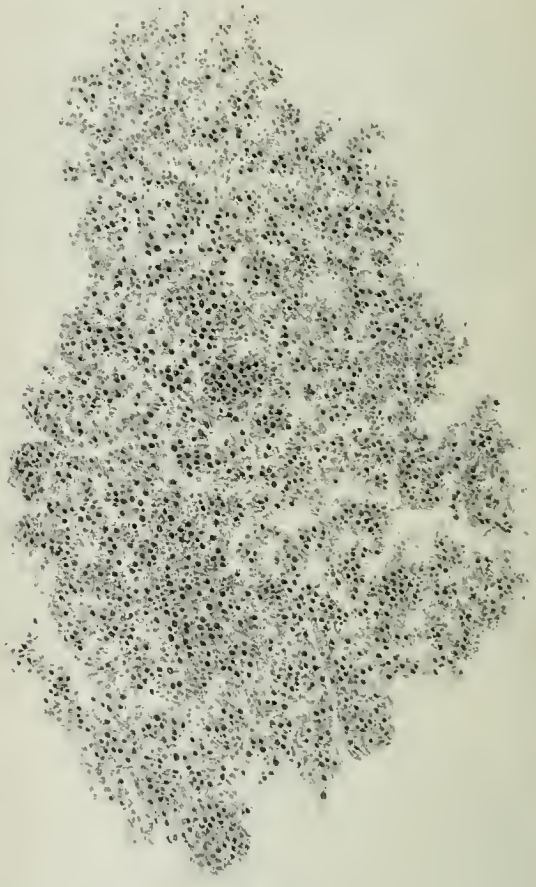

Fig. 7.—Photomicrographic sketch of a culture made from specimen that appeared to be the remains of a former hemorrhoidal operation. The specimen was washed in boiling water and then dipped in alcohol. After burning the alcohol off, the specimen was cut across and dropped into bouillon. A microscopic examination of the bouillon later shows numerous streptococci together with a few colon bacilli and other cocci, probably staphylococci.

blood vessels. Although retarding the blood stream will not of itself cause an inflammatory condition of the lining of the vessel, which is necessary to thrombosis, yet dilatation of the vessel favors thrombosis by aiding the entrance of bacteria.

That bacteria, the *exciting* cause, either directly or through their toxins, produce thrombosis has been definitely proven, and clinical experience shows that thrombosis is met with most frequently in those veins which, by reason of their location, are most exposed to infection. It would seem, from the anatomical conditions heretofore mentioned, the microscopic findings to be referred to, and from cur

knowledge of thrombosis elsewhere, that bacteria are the exciting cause of thrombosis in the anal and rectal veins. The rectal sinuses or diverticula (Fig. 3) serve as catch-basins or traps for the bac-

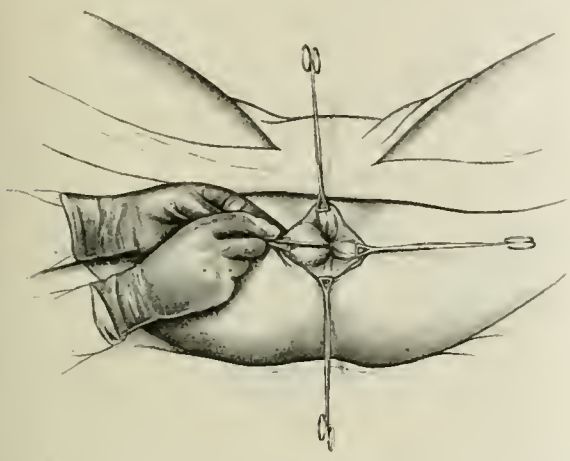

Fig. 8.—The hemorrhoidal field exposed and the hemorrhoid being incised.

teria. Here they give off toxins, which aid in producing irritation and congestion, to be followed by inflammation and their entrance into the stroma. The resistance of the tissues and vessels being lessened by the destructive processes produced by the bacteria, dilatation is favored and thrombosis follows. Besides this route, they may gain access to the stroma through some abrasion or otherwise, and produce a similar process of tissue destruction. Figs. 4, 5 and 6 show that bacteria are present in the sinuses and hemorrhoidal tissues and that the sinuses furnish a nidus for their incubation.

In specimens of hemorrhoids which were submitted by the writer to the Medical Research Laboratories of Chicago for examination there were found colon bacilli, diphtheroid bacilli, streptococci, staphylococci, diplococci, and other microorganisms. The same types of bacteria were found in specimens (Fig. 7) removed from points which seemed to be the stumps of former operations for hemorrhoids, as well as from the rectums of patients who did not

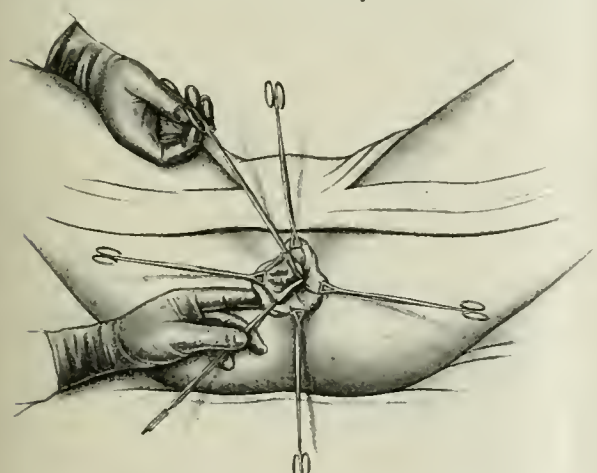

Fig. 9.—Forceps are placed on the incised covering of the pile, exposing the true hemorrhoidal mass.

present the clasical symptoms of hemorrhoids, but were suffering from some constitutional ailment. Removal of these points of infection corrected the constitutional or remote trouble.

The foregoing findings, it is believed, are sufficient to give rise to another classification of the hemorrhoidal condition—viz., that of non-infective and infective, as stated in a paper read before the

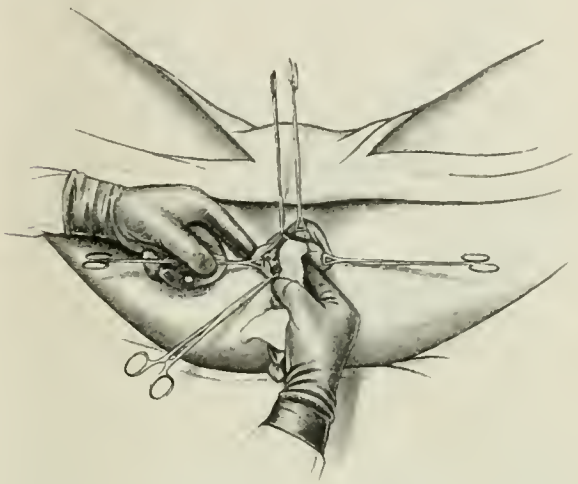

Fig. 10—The hemorrhoidal mass is removed with a piece of gauze on the index finger.

Ohio Valley Medical Association in November, 1916. This clasification is based, of course, on the relative virulence of the infection in the hemorrhoids. It is helpful to those who desire to compare and contrast the efficiency of the various methods of operative procedures in order to select the one which offers the best means for removing the infection as well as the tumor.

By the light of modern teaching, total removal of the hemorrhoid, when it is of the infective variety, is very essential. In the simple cutting off the top or removing part only of the hemorrhoid (as is done by the ligature, clamp and cautery, and many of the closed methods of operating), the infected base is left and closed over. This increases the danger of local and constitutional complications. How often has pruritus ani, ischio-rectal abscess, fistula or some other neurotic trouble been observed to follow one of the closed methods of operating? The writer has seen this not once, but many times.

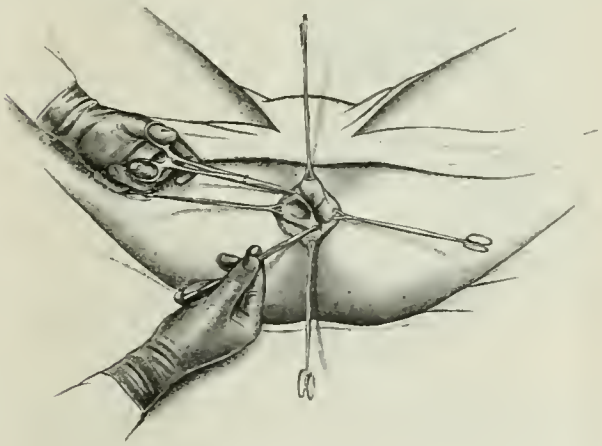

Fig. 11—Shows the appearance after the entire hemorrhoidal mass has been removed.

Locking in part of an infective hemorrhoid may give rise to a more serious condition than the original trouble. For example, tubercle bacilli when encapsulated are harmless; but when the encapsula-

tion is disturbed constitutional tuberculosis may develop.

Preparation of the Patient.—The patient is usually given a cathartic 12 to 18 hrs., and a colonic

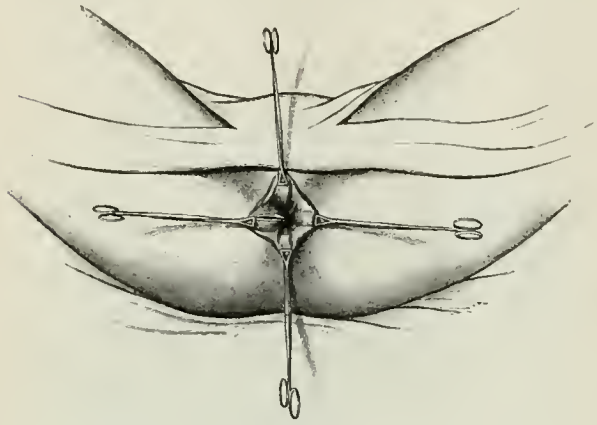

Fig. 12—Appearance after the excess of covering has been cut off.

flushing, until the water returns clear, 4 to 6 hrs. before operating. Simply flushing out the bowel 2 to 4 hrs. before operating seems to be quite satisfactory in many cases.

Anesthetic.—In an adult with a general hemorrhoidal condition—both internal and external piles—either local or general anethesia is used. We usually precede local anesthesia in an adult, with no contraindications. with a hypodermic injection of 1/4 gr. of morphine sulphate and 1 150 gr. of atropine sulphate twenty minutes before operating; or, give 1/6 gr. morphine sulphate and 1 150 gr. scopolamine $1^1/_2$ hrs. before, and repeat twenty minutes before operating.

As a rule, I use 40 m. to 60 m. of a 1 per cent. solution of cocaine muriate to "block off"[5] the field of operation. This amount of solution does not "water-log" the tissues nor disturb the anatomic landmarks and relations. The addition of adrenalin enhances its efficiency. The solution is deposited in

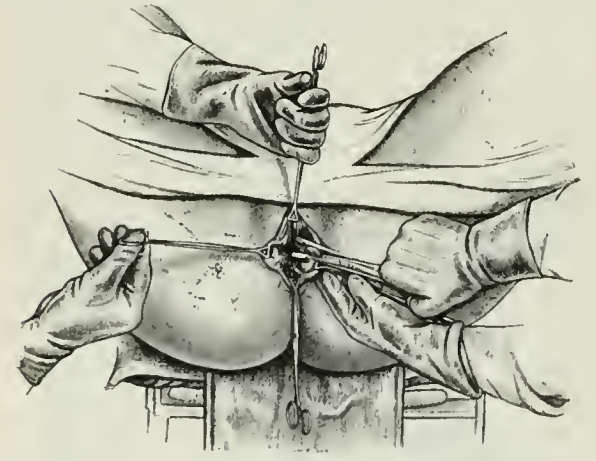

Fig. 13.—Illustrates method of prolapsing the hemorrhoids into view. The forceps attached to the left anal quadrant is grasped by the operator's left hand, the index finger is pushing the pile into the field and an ellipse is being removed from it.

and beneath the skin around the anus, and a few drops in the external sphincter in the anterior, posterior and lateral quadrants. If the operator is not familiar with the nerve supply and anatomy of this region, then he can add enough water to this quantity of solution to make a 1/8 or 1/10 of a 1 per cent. solution, and use this as he desires. When the patient is ready for the operation (he either

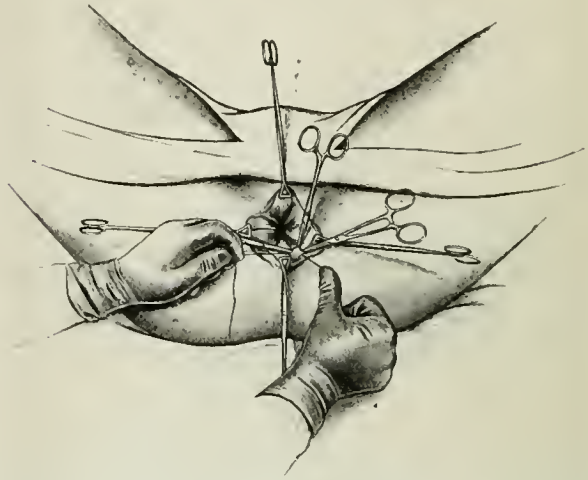

Fig. 14.—Illustrates a method of ligating a bleeding point by attaching two or more forceps to the field and separating them, which facilitates the tying.

being asleep or the field "blocked off") the rectum is dilated and washed out with either soap and water or lysol and water.

Treatment.—The treatment of hemorrhoid is preventive, palliative and curative.

Preventive Treatment: Prevention is a very important, if not the most important, factor in the treatment of hemorrhoids; yet authors of textbooks, so far as I have been able to ascertain, fail to give consideration to this therapeutic measure. Keeping the anus clean[6] and maintaining a respectable toilet is most important and essential, not only as a preventive measure in hemorrhoids, but in many other diseases of the anus and rectum, and in maintaining a respectable and sanitary condition of one's linen.

Briefly, people should be educated (*a*) to heed nature's call to evacuate the bowels; (*b*) not to hurry or force defecation by straining, etc.; (*c*) to keep the bowels regular by means of diet, exercise, periodic defecation, ablutions, etc. (Speaking of

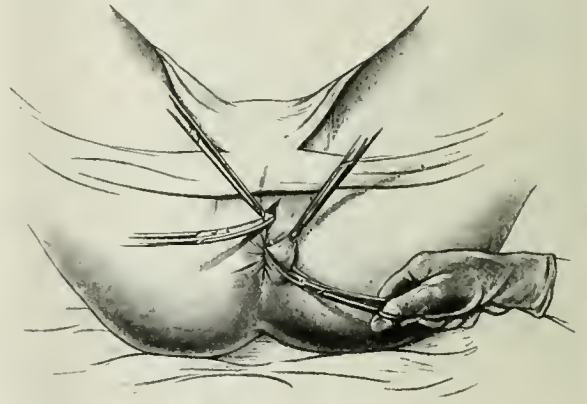

Fig. 15.—Illustrates the removal of an ellipse from the covering of a "fleshy pile," dissecting out the tumor mass, and the slit-like appearance after this dissection.

ablutions reminds me that Mr. Allingham says: "Many people seem to forget that the anus requires as much washing as any other part of the body."). (*d*) To avoid those articles of diet that tend to irri-

tate the anal canal; (*e*) not to use detergents that are hard or rough, or that may irritate, abrade, or infect the ano-rectal mucosa; (*f*) to know that neglecting hygienic and sanitary attention to the anus and rectum leads to a filthy condition of the parts, soiled linen, a luxuriant growth of bacteria, irritation, infection, cryptitis, and proctitis, to be followed by hemorrhoids, and other diseases of the anus and rectum and their metastatic sequelæ.

Palliative Treatment: This phase of the subject is very well considered in all text-books on diseases of the rectum.

Curative Treatment: Satisfactory curative treatment of hemorrhoids is difficult, as is evidenced by the multitudinous varieties of methods advocated by surgeons. This paper, however, will treat of the author's open operation only. Since new etiologic factors are now recognized in the causation of hemorrhoids, the pathology must be rewritten, and the operation made to conform to the new scientific developments.

The authors of our text-books divide hemorrhoids into the internal, the external, and the interno-external varieties. This classification, in the light of recent findings, is of but little service to those who desire to study and employ the most efficient method of operating. Nevertheless, it is on this text-book classification that practically all hemorrhoidal oper-

Fig. 16.—Rubber covered tampon.

ations have been based, and, doubtless, accounts for much of their inefficiency.

The writer in a former article[7] classified hemorrhoids according to their structure into those containing clotted blood, those containing fluid blood, those containing both fluid and clotted blood, and the "fleshy" variety. This classification is advantageous to those who desire to study the relative mechanical value of the various technics for overcoming the hemorrhoidal condition. It is the latest arrangement of the writer, however, that of simple (or non-infective) hemorrhoids and infective hemorrhoids, which determines the kind of operation which should be employed, and tells why.

Moreover, the foregoing findings emphasize the author's former claims for the advantages of the open method of operating. In the closed methods a section of the covering and a part of the hemorrhoid is removed, while the infected base is closed over or sealed in. While in the open method, not only a section of the covering is removed, but the entire infected mass or base as well, and the wound is left open for drainage. In the open method the amount of the covering to be removed is governed entirely by the operator. A simple incision in the covering is quite sufficient for the radical removal of the entire hemorrhoidal mass, should the surgeon so desire, as is shown in Figs. 8, 9, 10, 11, and 12.

But a more practical application of this procedure, and the one usually employed is as follows: T-forceps are applied, as shown in Fig. 13, then the forceps nearest the pile to be removed is grasped by the operator's hand, when the index finger naturally drops to the skin side of the hemorrhoid, and by slight pressure forces it into the field; then with a pair of scissors curved on the flat an ellipse commensurate with the size of the tumor, according to the surgeon's judgment, is removed. This incision, when properly executed, removes the ellipse from the covering, and most of the hemorrhoidal mass as well. Each tumor is treated in the same manner. Should there be a "spurter," it is picked up and ligated, as shown in Fig. 14. If a bleeding point is high in the rectum, a pair of curved forceps is applied to it, and another pair, of a similar curve, grasps the tissues near the one on the vessel and is so attached that the concave surfaces face each other; this forms an oval for the ligature to slip over and facilitates tying. This oval effect can be increased by divaricating the forceps. (The same principle may be applicable when ligating bleeding vessels in other cavities.) The internal tumors removed, the T-forceps are taken off, and the external piles excised, as shown in Fig. 15. In eliminating these growths, sufficient of the tumor mass is removed so that the anal region will present a normal appearance when the operation is completed.

Should a ring of flesh completely encircle the anus and extend distally for an inch or more, as it frequently does, it is removed by the same technic.

The field is then cleared of blood clots and a rubber-covered tampon, Fig. 16, which dresses the field in extension, is introduced into the rectum. Hot wet dressings, a piece of protective and a snugly fitting T-bandage are now applied.

The dressings and tampon are removed in from 18 to 24 hours and hot fomentations continued.

In 6 or 8 hours thereafter, an enema of 3 oz. of olive oil, and a laxative are given. The patient does not use a bed pan, but gets out of bed and goes to the water-closet or uses a commode; wet cotton is employed as a detergent.

Hot fomentations are applied every 4 to 6 hours for a day or so. The average patient is dismissed on the third or fourth day after the operation. Occasionally, one will remain a day or two longer; on the other hand, they frequently leave earlier.

Since no tissue is under stress, nor cauterized or ligated en masse, and there are not needle holes through the mucous membrane to carry in infection and no infection closed in, there is less likelihood of complications, and the patient should, and does, according to clinical observations, recover earlier, with less pain and a better result.

HAYFEVER AND ITS RELATION TO 100 OF THE MOST COMMON PLANTS, TREES AND GRASSES.

By WILLIAM SCHEPPEGRELL, A.M., M.D.,

NEW ORLEANS.

PRESIDENT, AMERICAN HAYFEVER-PREVENTION ASSOCIATION, EX-PRESIDENT, AMERICAN ACADEMY OF OPHTHALMOLOGY AND OTO-LARYNGOLOGY, CHIEF OF HAYFEVER CLINIC CHARITY HOSPITAL.

THE etiological relation of pollens to hayfever is evidently well established, but the special plants that are responsible are not well known as indicated by the inquiries which we are constantly receiving. While the ragweeds (Ambrosia) are accepted as the principal cause of hayfever, our correspondents inquire as to the toxicity of numerous harmless plants such as the honeysuckle, lily, rose, daisy, strawberry, golden rod, crysanthemum, resin weed,

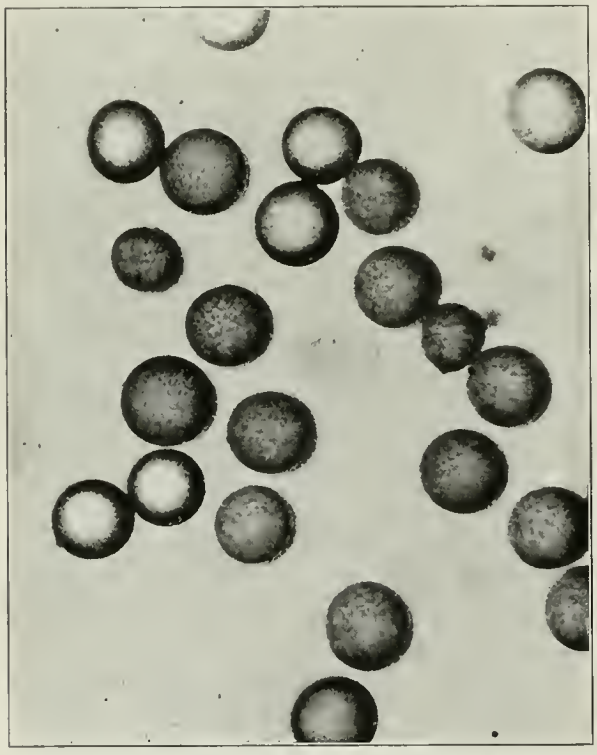

FIG. 1.—Pollen of red maple (*Acer rubrum*). Magnified 500 diam. A cause of mild hayfever.

aster, evening primrose, etc. As some of these are listed as hayfever plants even in our standard textbooks, we have decided to report the result of our investigations as a practical guide on this subject.

Generally speaking, the characteristics of hayfever plants are as follows:* (1) They are wind-pollinated; (2) very numerous; (3) the flowers (florescences)are inconspicuous, without bright color or scent, and (4) the pollen is formed in large quantities.

While all the hayfever plants are included in the above classification, there are many plants with these qualities whose pollen is harmless from a hayfever standpoint.

The pines, for instance, are wind-pollinated, numerous, with inconspicuous flowers (aments) which

*"Hay-Fever and Its Prevention," Wm. Scheppegrell, M.D., United States Public Health Reports, July 21, 1916.

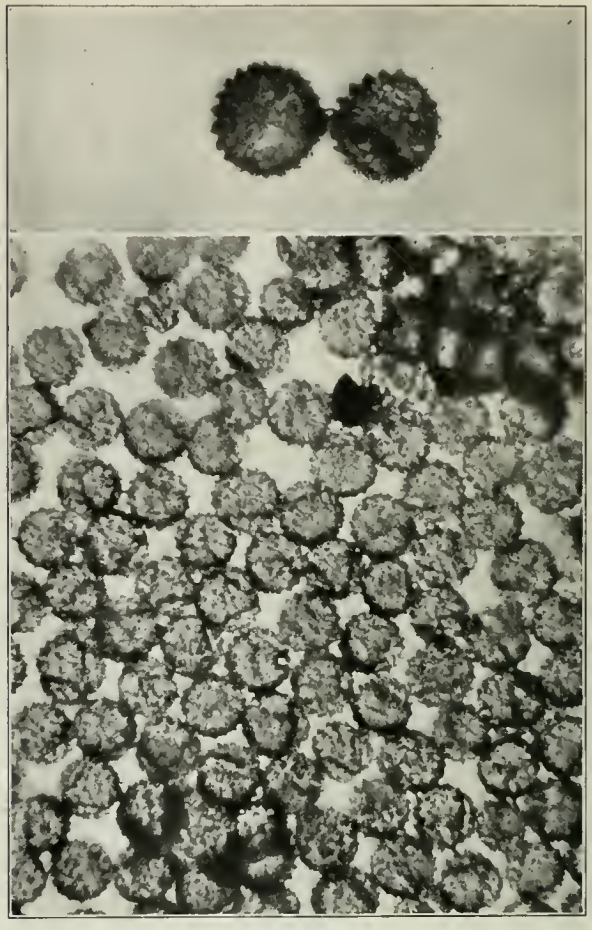

FIG. 2.—Pollen of the ragweed, × 500 diameters. The upper two (A) have a magnification of 1000 diameters. (From the biological laboratory of the American Hayfever Prevention Association.)

FIG. 3.—Pollen of sagebrush (*Artemisia tridentata*). Magnified 500 diam. The artemisias are the principal cause of hayfever in the Pacific and Rocky Mountain States.

are without bright colors or scent and whose pollen is formed in great quantities, yet, as shown in our list, they give a negative reaction in hayfever.

When it has been found, therefore, that a plant

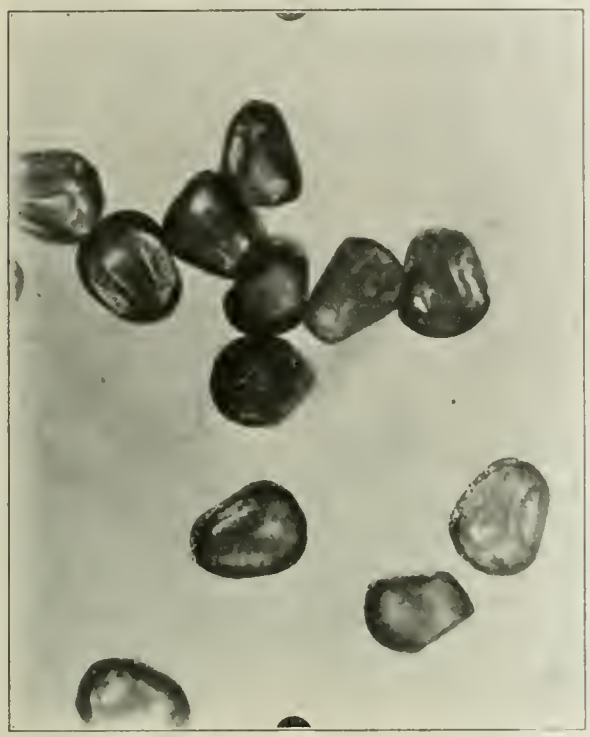

Fig. 4.—Pollen of field oats (*Avena sativa*). Magnified 500 diam. A member of the grass family which is the chief cause of early hayfever.

is wind-pollinated, the effect in hayfever must be determined by the biological test. A small amount of the pollen is applied to the nostril of a hayfever

Fig. 5.—Pollen of foxtail grass (*Chaetochloa glauca*). Magnified 500 diam. An important cause of early hayfever.

subject or to the conjunctival sac, and, if the reaction is positive, the pollen is a potential cause of hayfever. Instead of the conjunctival or nasal test, the skin is often preferred, a drop of the extract

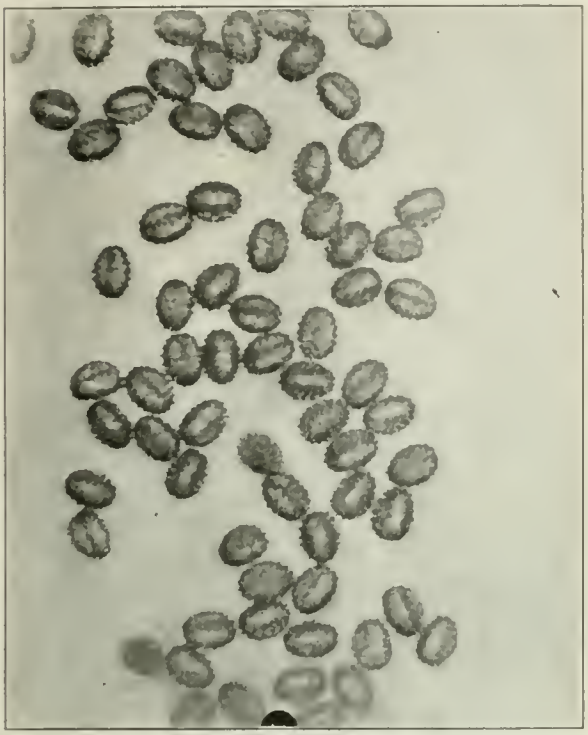

Fig. 6.—Pollen of daisy fleabane (*Erigeron strigosus*). Magnified 500 diam. Common cause of hayfever in children from direct inhalation.

of the pollen being applied to the scarified skin or injected intradermically.

When the pollen is applied to the eye, a positive

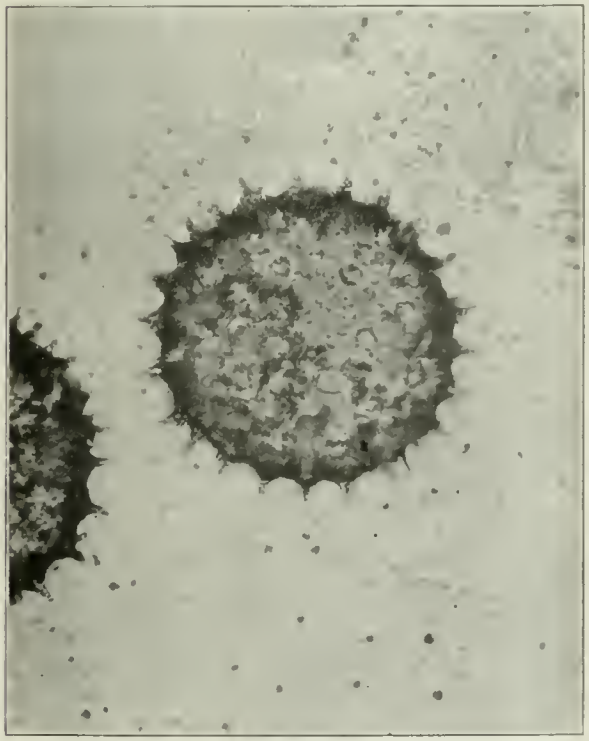

Fig. 7.—Pollen of cotton. (*Gossypium peruvianum*). Magnified 500 diam. Harmless in hayfever.

reaction is indicated by a transient injection of the conjunctiva. In the nostril, it is shown by a temporary hayfever reaction which lasts from ten minutes to several hours according to the amount of pollen inhaled and its toxicity.* The skin reaction is shown by a slight swelling resembling uticaria accompanied by a sensation of heat and itching.

The pollens that are responsible for hayfever are not toxic to all hayfever subjects. The majority of persons sensitive to the ragweed (Ambrosia) pollen are not affected by the grass (gramineæ) pollens, and many persons who have vernal hayfever due to the grass pollens are relieved of their hayfever in the fall, in spite of the fact that the air contains large numbers of ragweed pollens.

Ignorance of the fact that the plants which cause hayfever must necessarily be limited to those which are wind-pollinated, is responsible for much of the

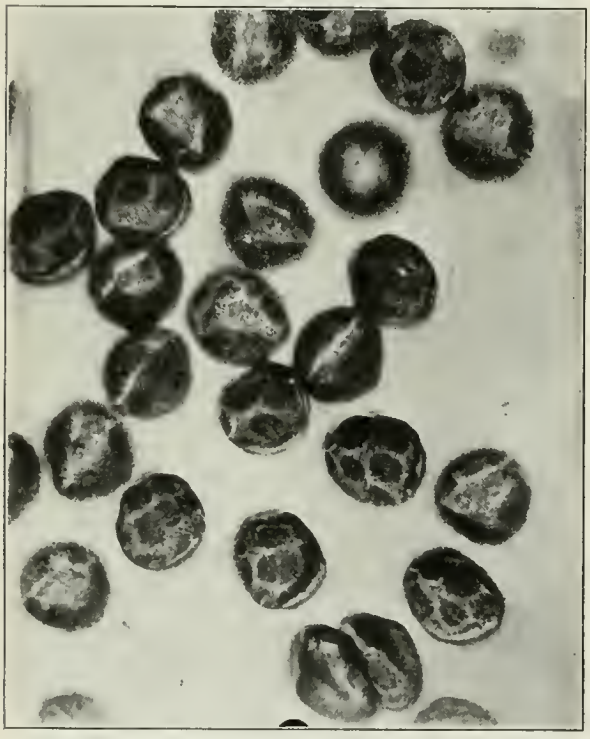

Fig. 8.—Pollen of black walnut (*Juglans nigra*). Magnified 500 diam. Important cause of hayfever in some sections (Central California, etc.).

confusion on this subject. While the roses, for instance, are not wind-pollinated, being typical insect-pollinated plants, the term "Rose-cold" is still commonly used, even by physicians, for the vernal type of hayfever due to the pollen of the grasses (gramineæ).

While ordinary reasoning will show that only those pollens which are inhaled in normal respiration can cause hayfever, this has been corroborated by our atmospheric-pollen plates which are exposed daily at various stations.* The procession of the pollens is carefully recorded from the pollination of the trees in early spring, followed by the grasses and ending with the ragweeds in the fall, and naturally only those of wind-pollinated plants are found.

*"Toxicity" in pollens refers to their reaction in hayfever subjects. The existenceof a true toxin in hayfever is still under investigation.

*"Hay-Fever and Hay-Fever Pollens," Wm. Scheppegrell, M.D. *Archives of Internal Medicine*, June 15, 1917.

While wind-pollinated plants alone are responsible for hayfever, we have tested many others which have been added to the list. Some of these will cause

Fig. 9.—Pollen of Coulters pine (*Pinus coulteri*). Magnified 125 diam. Harmless in hayfever. Shows "winged" pollens characteristic of the pine family.

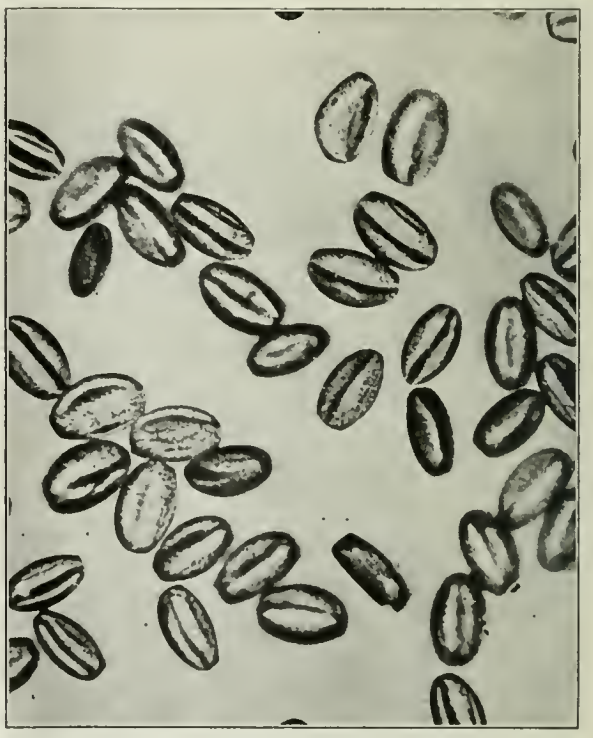

Fig. 10.—Pollen of cottonwood (*Populus deltoides*). Magnified 500 diam. This is a common form of the tree pollens. (Oak, willow, box elder, etc.)

an acute attack of hayfever on direct inhalation which not infrequently happens with children. In this class are included such plants as the daisy

PARTIAL LIST OF PLANTS TESTED FOR HAYFEVER REACTION AT THE BIOLOGICAL LABORATORY OF THE AMERICAN HAYFEVER PREVENTION ASSOCIATION

Botanical Names	Principal Common Names	Surface of Pollen	Size in Microns	Hayfever Reaction	Pollination	Amount of Pollen	Seasons of Bloom	Geographical Distribution	Remarks
Acer drummondii	Hard maple	Smooth, spherical	45	Mild	Wind	Very large	March, April	Mo. to Ga., Fla. and Tex.	Occasional cause of early hayfever.
Acer negunda	Box elder	Smooth, ovoid	25x40	Negative	Wind	Very large	April, May	Me. and Ont. to Manitoba; south to Mex., Fla. and Tex.	Harmless in hayfever.
Acer rubrum	Red maple	Smooth, spherical, Fig. 1	40	Mild	Wind	Very large	March, April	Nova Scotia to Neb., Fla. and Tex.	Occasional cause of mild early hayfever.
Acnida tamariscina	Western water hemp	Smooth, spherical	25	Mild	Wind	Very large	July, Sept.	Ill. to Dak., Tex. and N. M.	A minor cause of mild hayfever.
Allenrolfea occidentalia	Grease weed	Smooth, spherical	20	Medium	Wind	Very large	March, Nov.	Cal., Ore. to Tex.	A cause of hayfever in Pacific and Rocky Mt. States.
Amaranthus spinosus	Spiny amaranth	Smooth, spherical	20	Mild	Wind	Large	June, Sept.	Me. to Minn., Fla. and Tex.	Accessory cause of mild hayfever.
Ambrosia elatior	Common rag-weed	Spiculated, spherical Fig. 2	15	Very active	Wind	Profuse	Aug., Oct.	Nova Scotia to Fla.; west to Kan.	Principal cause of autumnal hayfever east of Kan.
Ambrosia psilostachya	Western rag-weed	Spiculated, spherical	26	Very active	Wind	Large	July, Oct.	Ill. to Sask., Tex., Mex., Cal. and La.	Important hayfever weed west of Kan.
Ambrosia trifida	Giant rag-weed	Spiculated, spherical	20	Very active	Wind	Profuse	Aug., Oct.	Quebec to Fla.; west to Neb., Col. and N. M.	Important cause of autumnal hayfever.
Andropogon halepensis	Johnson grass	Smooth, spherical	45	Positive	Wind	Very large	June, Sept.	N. J., Ky., E. Kan. and Ariz.; south to Fla. and Tex.	Common cause of early hayfever.
Artemisia biennis	Biennial wormwood	Spiculated, spherical	15	Positive	Wind	Large	Aug., Oct.	Manitoba to Nova Scotia, Mo., Ky. and Del.	A cause of typical hayfever.
Artemisia dracunculoides	Indian hair tonic	Smooth, 3-lobed	11	Severe	Wind	Very large	June, Sept.	Manitoba to Col., Ill., Mo., Neb., Tex. and Cal.	Common cause of hayfever in the Pacific and Rocky Mt. States.
Artemisia frigida	Wormwood sage	Smooth, 3-lobed	20	Severe	Wind	Very large	July, Oct.	Minn., Idaho, Neb., Tex. and Ariz.	A cause of hayfever west of Kan. Also found at high altitudes (6,000 ft.).
Artemisia heterophylla	Mugweed	Smooth, 3-lobed, Fig. 3	22	Severe	Wind	Very large	July, Oct.	Cal. to Brit. Col. and Nev.	Important hayfever weed, west of Kan.
Artemisia ludoviciana	Dark-leaved mugwort	Smooth, 3-lobed	18	Severe	Wind	Very large	July, Oct.	Cal. and Rocky Mt. States	Common cause of hayfever in Pacific and Rocky Mt. States.
Artemisia tridentata	Sagebrush	Smooth, 3-lobed	22	Severe	Wind	Very large	July, Sept.	Neb. to Col., Utah and Cal.; north to Minn.	Important cause of hayfever in the Rocky Mt. States.
Aster ericoides	Michaelmas daisy	Spiculated, spherical	15	Positive	Insect	Small	Sept., Dec.	Ohio to Car., Mich.	Hayfever on direct inhalation only.
Aster novæanglia	New England aster	Spiculated, spherical	18	Positive	Insect	Small	Aug., Oct.	S. C., Ala., Kan. and Col.	Hayfever on direct inhalation only.
Avena sativa	Oats	Smooth, spherical Fig. 4	35	Positive	Wind	Abundant	May, June	Cultivated	A cause of early hayfever.
Capriola dactylon	Bermuda grass	Smooth, spherical	25	Positive	Wind	Abundant	June, July	Mass. and N. Y. to Mo., Fla. and Mex.	A cause of early hayfever.
Celtis Mississippiensis	Hackberry	Smooth, spherical	25	Negative	Wind	Very large	April	Va. to Ill. and Mo.; south to Fla. and Tex.	Harmless in hayfever
Centaurea cyanus	Cornflower	Smooth, ovoid	20x40	Positive	Insect	Small	July, Sept.	Que. to Ont., N. Y., Neb. and Va.	Hayfever only on direct inhalation.
Chætochlon glauca	Foxtail grass	Smooth, spherical, Fig. 5	40	Positive	Wind	Large	July, Sept.	North America generally except extreme North.	Common cause of early hayfever.
Chætochloa magna	Giant foxtail grass	Smooth, spherical	26	Positive	Wind	Large	July, Aug.	Del. and Va. to Fla. and Tex.	Occasional cause of hayfever.
Chenopodium album	White goosefoot Lamb's quarters	Smooth, spherical	19	Mild	Wind	Large	June, Sept.	Common throughout North America, except the extreme north.	A cause of mild hayfever.
Chenopodium ambrosioides	Mexican tea	Smooth, spherical	20	Mild	Wind	Large	Aug., Oct.	Me. to Fla.; west to Cal.	A cause of mild hayfever.
Chrysanthemum leucanthemum	Ox-eye daisy	Spiculated, spherical	24	Positive	Insect	Small	May, Nov.	Common throughout north. Less abundant in south and west	Hayfever on direct inhalation.
Cirsium lanceolatum	Horse thistle	Smooth, ovoid	20x30	Negative	Insect	Small	June, Oct.	Newfoundland to Ga., Minn., Neb., Ore. and Cal.	Harmless in hayfever
Cupressus macrocarpa	Monterey cypress	Smooth, spherical	22	Negative	Wind	Large	March, April	Pacific Coast	Harmless in hayfever.
Cyperus rotundus	Nut grass (sedge)	Smooth, prismatic	22	Negative	Wind	Large	July, Sept.	Va. to Fla., Mo., Kan. and Tex.	Accused of causing hayfever but harmless.
Datura stramonium	Jimson weed	Smooth, spherical	18	Positive	Insect	Small	June, Sept.	Nova Scotia to Fla., west to Minn. and Tex.	Reaction only on direct inhalation.
Dianthus chinensis	Chinese pink	Smooth, spherical	40	Positive	Insect	Small	June, Aug.	Cultivated	Hayfever only on direct inhalation.
Drucopis amplexicaulis	Blackeye Susan	Spiculated, ovoid	25x35	Active	Insect	Medium	June, Aug.	Mo. to Okla., La. and Tex.	Causes hayfever only on direct inhalation.
Erianthus compactus	Plume grass	Smooth, spherical	28	Positive	Wind	Abundant	Sept.	N. J. to Fla. and Tex.	A minor cause of early hayfever.
Erigeron canadensis	Horseweed	Spiculated, ovoid	17x24	Positive	Wind	Large	June, Nov.	Common throughout North America, except in extreme north	Contributory cause of hayfever.
Erigeron strigosus	Daisy fleabane	Spiculated, ovoid, Fig. 6	15x20	Positive	Insect	Small	May, Nov.	Nova Scotia to Brit. Col., Fla., Tex. and Cal.	Frequent cause of hayfever in children from direct inhalation.
Eupatorium serotinum	Thoroughwort	Spiculated, ovoid	18x21	Positive	Wind and insect	Medium	Sept., Nov.	Del. to Fla., Minn., Iowa, Kan. and Tex.	Cause of hayfever but is not sufficiently abundant to be of importance.
Eupatorium sessilifolium	Upland boneset	Spiculated, spherical	20	Positive	Insect	Medium	Aug., Oct.	Vt. to Mass., Pa., Ga., Ala. and Mo.	Hayfever only on direct inhalation.
Franseria acanthicarpa	False ragweed	Spiculated, spherical	15	Positive	Wind	Large	July, Sept.	Sask. to Neb. and Tex.; west to Brit. Col. and Cal.	Common cause of hayfever in the Pacific and Rocky Mt. States.

PARTIAL LIST OF PLANTS TESTED FOR HAYFEVER REACTION AT THE BIOLOGICAL LABORATORY OF THE AMERICAN HAYFEVER-PREVENTION ASSOCIATION

Botanical Names	Principal Common Names	Surface of Pollen	Size of Microns	Hayfever Reaction	Pollination	Amount of Pollen	Seasons of Bloom	Geographical Distribution	Remarks
Franseria dumosa	Sandbur	Spiculated, spherical	18	Positive	Wind	Large	March, June	Utah to Cal. and Ariz.	Common cause of hayfever in the Pacific and Rocky Mt. States.
Fraxinus americana	White ash	Smooth, spherical	20	Negative	Wind	Very large	May, June	Nova Scotia to Ont., Minn., Fla., Kan. and Tex.	Harmless in hayfever.
Gossypium peruvianum	Cotton	Spiculated, spherical Fig. 7	110	Positive	Insect	Small	June, July	Southern States	Negligible in hayfever on account of large size of pollen.
Grindelia squarrosa	Resin weed	Spiculated, spherical	20	Positive	Contact	Small	June, Sept.	Ill. and Minn. to Mo., Ariz. Adventive in N. J., Pa., N. Y.	In spite of popular belief in certain sections it does not cause hayfever.
Helenium quadridentatum	Sneezeweed	Spiculated, spherical	25	Very active	Insect	Small	July, Oct.	Va., Fla., Mo., Kan. and Tex.	Causes hayfever only on direct inhalation.
Helianthus annuus	Common sunflower	Spiculated, spherical	40	Very active	Insect and wind	Medium	July, Sept.	Minn. to N. D., Idaho, Mo., Tex. and Cal.	Causes hayfever only in close proximity.
Helianthus angustifolius	Perennial sunflower	Spiculated, spherical	40	Positive	Insect	Medium	Aug., Oct.	L. I. to Fla., Ky. and Tex.	Hayfever only in direct inhalation or close proximity.
Hibiscus palustris	Marshmallow	Spiculated, spherical	170	Positive	Insect	Small	Aug., Sept.	Mass. to Fla. to La., Iod., Mo.	Negligible on account of large size of pollen
Hicoria ovata	Hickory	Smooth, spherical	35	Positive	Wind	Abundant	May	Que. to Ont. to Fla. and Tex.	Accessory cause of early hayfever.
Hemalocenchrus virginicus	White grass	Smooth, spherical	26	Positive	Wind	Large	Aug., Sept.	Me. to Ont., Fla and Tex.	Minor cause of hayfever.
Hymenochloea salsola	Grease weed	Smooth, spherical	20	Mild	Wind	Large	July, Sept.	Cal., Ariz., Nev.	Minor cause of hayfever in the Pacific and Rocky Mt. States.
Ilex opaca	American holly	Rough, 3-lobed	20x30	Negative	Insect	Small	April, June	Mass. to Fla., Pa., Ind. Mo. and Tex.	Harmless in hayfever.
Ipomœa purpurea	Morning-glory	Spiculated, spherical	75	Positive	Insect	Small	June, Oct.	Nova Scotia to Fla.; west to Ont., Neb., Tex.	Occasional reaction from direct inhalation.
Iva axillaris	Poverty weed	Spiculated, spherical	20	Positive	Wind	Large	May, Sept.	Manitoba and N. D. to Neb., N. M. and Cal.	Common cause of hayfever in the Pacific and Rocky Mt. States.
Iva ciliata	Rough marsh elder	Spiculated, spherical	25	Active	Wind	Profuse	Aug., Oct.	Ill. to Neb., La. and N. M.	A cause of hayfever.
Iva xanthiifolia	Burweed marsh elder	Spiculated, ovoid	15x20	Positive	Wind	Large	July, Sept.	Wis., Neb., N. M. and Utah	Important cause of hayfever west of Kan.
Juglans nigra	Black walnut	Smooth, spherical, Fig. 8	40	Positive	Wind	Abundant	April, May	Mass., Ont. and Minn. to Tex. and Fla.	A cause of early hayfever.
Juniperus virginiana	Red cedar	Smooth, spherical	20	Positive	Wind	Abundant	April, May	Nova Scotia to Ont. and S. D. to Fla. and Tex.	Occasional cause of early hayfever.
Kalmia latifolia	Mountain laurel	Smooth, 3-lobed	25	Negative	Insect	Small	May, June	New Brunswick to Ont. Ind., Ky., Fla. and La.	Harmless in hayfever
Lagerstræmia indica	Crepe myrtle	Smooth, ovoid	22x31	Negative	Insect	Small	April, May	From Md., southward	Harmless in hayfever.
Leontodon taraxacum	Dandelion	Spiculated, hexagonal	46	Marked	Insect	Small	Jan., Dec.	All parts of the world	Causes reaction only on direct inhalation.
Leptochloa filiformis	Feather grass	Smooth, spherical	20	Positive	Wind	Abundant	June, July	Va. to Ill. and Cal.; south to Fla. and Mex.	Accessory cause of early hayfever.
Ligustrum amurense	Japanese privet	Smooth, ovoid	23x37	Negative	Insect	Small	June, July	Cultivated	Harmless in hayfever.
Liquidambar styraciflua	Sweet gum	Smooth, spherical	30	Negative	Wind	Abundant	April, May	Conn. and N. Y. to Fla., Ill., Mo. and Mex.	Harmless in hayfever.
Lonicera flava	Yellow honeysuckle	Spiculated, spherical	55	Mild	Insect	Small	May	N. C., to Ky., Mo., Ga. and Ala.	Causes mild reaction only on direct inhalation.
Magnolia virginiana	Laurel magnolia	Smooth, ovoid	45x83	Negative	Wind and insect	Abundant	May, June	Eastern and southern States.	Harmless in hayfever.
Mirabilis	Four o'clock	Spiculated, spherical	185	Negative	Insect	Small	June, Oct.	Cultivated	Harmless. One of the largest pollens investigated.
Morus alba	White mulberry	Smooth, spherical	19	Negative	Wind	Abundant	May	Me. and Ont. to Fla.	Harmless in hayfever.
Oenothera biennis	Evening primrose	Smooth, triangular	130	Negative	Insect	Small	June, Oct.	Fla., Minn., Ark. and Tex.	Harmless in hayfever.
Osmunda cinnamomea	Cinnamon fern	Spiculated, ovoid	35x53	Negative	Insect	Abundant	May, June	Newfoundland to Minn., Gulf States and N. M.	Spores harmless in hayfever.
Oxydendron arboreum	Sourwood	Smooth, 3-lobed	25	Negative	Insect	Small	May, June	New Brunswick to Ont., Ind., Ky., Fla. and La.	Harmless in hayfever.
Panicum crus-galli	Cockspur grass	Smooth, spherical	26	Positive	Wind	Abundant	Aug., Oct.	North America generally	A cause of early hayfever.
Panicum repens	Marsh grass	Smooth, spherical	47	Positive	Wind	Large	July	Salt marshes of southern states	Occasional cause of hayfever.
Parthenium hysterophorus	False wormwood	Spiculated, spherical	20	Positive	Wind	Medium	July, Sept.	Pa. to Ill., Mo., Fla., Tex. Throughout tropical America	In some sections this is a perennial bloomer and may cause hayfever at any season.
Paspalum vasyanum	Small bull grass	Smooth, spherical	26	Positive	Wind	Abundant	Aug., Sept.	Va. and Tenn. to Fla. and Tex.	Common cause of early hayfever.
Phœnix	Date palm	Smooth, ovoid	23x50	Negative	Mild	Large	June	Cultivated	Harmless in hayfever.
Pinus palustris	Long-leaf pine	Smooth, spherical (winged)	40	Negative	Wind	Very abundant	March, April	Va. to Ala., Fla. and Tex.	Negative in hayfever.
Plantago lanceolata	Lance-leaved plantain	Smooth, spherical	13	Mild	Wind and insect	Medium	April, Nov.	Northwest, Fla. and Kan.	Occasional cause of mild hayfever.
Poa annua	Annual meadow grass	Smooth, spherical	24	Positive	Wind	Abundant	May, Oct.	Throughout North America	Common cause of early hayfever.
Polygonum aviculare	Knot-grass	Smooth, spherical	17	Mild	Wind and insect	Medium	June, Oct.	Common almost throughout North America.	Occasional cause of mild hayfever.
Populus deltoides	Yellow cottonwood	Smooth, ovoid, Fig. 10	22x32	Positive	Wind	Abundant	April, May	Que. to Manitoba, south to Conn., Fla. and Tenn.	Only about one-half of the trees (male) furnish pollen (positive).

PARTIAL LIST OF PLANTS TESTED FOR HAYFEVER REACTION AT THE BIOLOGICAL LABORATORY OF THE AMERICAN HAYFEVER-PREVENTION ASSOCIATION

Botanical Names	Principal Common Names	Surface of Pollen	Size in Microns	Hayfever Reaction	Pollination	Amount of Pollen	Seasons of Bloom	Geographical Distribution	Remarks
Prosopis glandulosa	Prairie mesquite	Smooth, ovoid	20x50	Negative	Insect and wind	Medium	April, June	Kan. to Tex., Ariz., Cal. and Tex.	Harmless in hayfever.
Prunus avium	Wild cherry	Smooth, ovoid	12x23	Negative	Insect and wind	Medium	April, May	Ont. to Conn., Pa. and Va.	Harmless in hayfever.
Quercus nigra	Water oak	Smooth, ovoid	18x34	Medium	Wind	Abundant	April, May	Del. to Ky., Mo., Fla. and Tex.	Occasional cause of early hayfever.
Rhus typhina	Staghoro sumac	Smooth, ovoid	30x40	Mild	Insect	Medium	June	Nova Scotia to Ga.; west to S. D., Iowa and N. H.	Negligible in hayfever.
Robinia pseudacacia	Locust tree	Smooth, ovoid	10x30	Negative	Insect	Medium	May, June	Pa. to Ga.; west to Iowa, Mo. and Okla.	Harmless in hayfever.
Rosa hybrida	Garden rose	Smooth, ovoid	20x26	Negative	Insect	Medium	April, Oct.	Cultivated	Its influence in hayfever is a popular myth.
Rudbekia laciniata	Goldenglow	Spiculated, spherical and ovoid	30	Positive	Insect	Small	June, Aug.	Cultivated	Hayfever only on direct inhalation.
Rubus procumbens	Blackberry	Smooth, ovoid	10x30	Negative	Insect	Small	April, May	Ont. to Lake Superior; south to Va., La. and Tex.	Harmless in hayfever.
Rubus neglectus	Wild raspberry	Smooth, ovoid	15x35	Negative	Insect	Small	May, July	Vt. to Ont., Pa. and Ohio	Harmless in hayfever.
Rumex crispus	Yellow dock	Smooth, spherical	25	Mild	Wind	Abundant	June, Aug.	Nearly throughout the United States	Minor cause of hayfever.
Salix nigra	Blackwillow	Smooth, ovoid	20x32	Mild	Wind	Abundant	April, May	New Brunswick to western Ont., N. D., Fla. and Tex.	Occasional cause of early hayfever.
Sambucus canadensis	American elder	Smooth, ovoid	15x20	Negative	Insect	Small	June, July	Nova Scotia to Fla., Kan. and Tex.	Harmless in hayfever.
arcobatus vermicularis	Grease weed	Smooth, spherical	28	Mild	Wind	Large	Sept., Oct.	Neb., Wyo. to Nev. and N. M.	A cause of hayfever in the Rocky Mountain States.
Scirpus mucronatus	Bog bullrush	Smooth, spherical	20	Negative	Wind	Medium	July, Sept.	Pa.	Harmless in hayfever.
Solanum carolinense	Horse nettle	Smooth, ovoid	20x30	Positive	Contact and insect	Small	June, July	Nova Scotia to Fla., west to Ill., Neb. and Tex.	Hayfever on direct inhalation.
Solidago canadensis	Canadian goldenrod	Spiculated, ovoid	18x22	Positive	Insect	Medium	Aug., Oct.	Va., Tenn. and S. D.	Hayfever on direct inhalation or close proximity as from room decorations.
Sonchus asper	Sow thistle	Spiculated, spherical	30	Active	Insect	Small	May, Nov.	Widely distributed in all parts of United States	Causes reaction only on direct inhalation.
Sporobulus angustus	Smut grass	Smooth, spherical	25	Positive	Wind	Abundant	June, July	Va. to Fla.; west to Mo. and Cal.	Common cause of early hayfever.
Trifolium pratense	Red clover	Smooth, ovoid	40x50	Negative	Insect	Small	April, Nov.	Common throughout north and south.	Harmless in hayfever.
Triticum vulgare	Wheat	Smooth, spherical	50	Positive	Wind	Large	July, Aug.	Cultivated	A cause of hayfever but potential area limited by large size of pollen.
Ulmus americana	American elm	Smooth, spherical	30	Negative	Wind	Abundant	March, April	Newfoundland to Manitoba, Fla. and Tex.	Harmless in hayfever.
Vaccinium pallidum	Blueberry	Smooth, spherical	35	Negative	Insect	Small	May, June	Va. to S. C.	Harmless in hayfever.
Vernonia noveboracensis	Iron weed	Spiculated, spherical	40	Positive	Insect	Few	July, Sept.	Mass. to Pa., N. C., W. Va., Miss. and Mo.	Hayfever only on direct inhalation.
Xanthium pennsylvanicum	Cockle burr	Spiculated, spherical	36	Positive	Wind	Abundant	Aug., Oct.	Minn. to N. Y., Mo. Col. moist soil)	Less active reaction than the ragweed. Large size of pollen limits potential area.

fleabane (*Erigeron strigosus*) golden rod (*Solidago canadensis*), aster (*Chrysopsis*), cornflower (*Centaurea*), sunflower (*Helianthus*), etc.

The *size of the pollens* are given in this list, as this has an important bearing on their potential area. That the common ragweed (*Ambrosia elatior*) is so widespread in its noxious effect is greatly influenced by its small size (15 microns). On this account, it is so buoyant that when the wind reaches a velocity of 20 miles per hour, it will travel several miles, while the pollen of the cocklebur, on account of its greater size (34 microns), will travel only one-fourth of this distance and therefore infect only one-sixteenth of the area. The pollen of corn (80 microns) under the same conditions will traverse only one-thirtieth of the distance and spread over only one nine-hundredth of the area infected by the ragweed. On this account the corn pollen, although noxious to many persons, is rarely responsible for hayfever.

The *quantity of pollen* generated by the plants is also stated in this list. The amounts are relative and based on the number of pollen given off by the ragweeds. The number of pollens on the daisies and sunflowers, for instance, are many thousands, but our investigations have shown that a single ragweed plant (*Ambrosia elatior* or *trifida*) may generate 4,000,000,000 pollens daily,* so that the quantity of the former are listed as "small" and of the latter "abundant."

The amount of pollen generated by a plant is an important item in its potential responsibility of hayfever. In spite of its toxicity and great buoyancy, the ragweeds would not be an important factor in hayfever were it not for the enormous quantity which they distribute into the air. Our atmospheric-pollen plates (Louisiana Stations) have shown that from September 22, 1916, to October 22, 1916, there were an average of 33 ragweed pollen per square yard of air, while on days of unusual atmospheric disturbances the number rose as high as 365.

The *period of bloom* (florescence) of the various plants is given as this will assist in establishing

*The pollen of the common ragweed (*Ambrosia elatior*) measures 15 microns, and there are about 420 millions to the cubic centimeter. The plant therefore generates about 2.5 c.c. of pollen per day.

the differential diagnosis of hayfever. The common ragweed (*Ambrosia elatior*), for instance, in most locations blooms from August 15 to October. An attack of hayfever in June or July could therefore not be due to the ragweeds, but to some other plant blooming during these months.

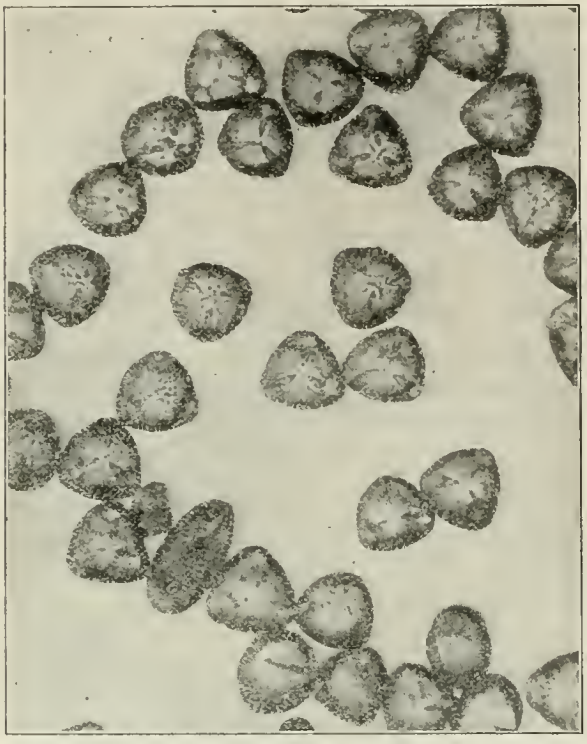

FIG. 11.—Pollen of flowering crab-apple (*Pyrus japonica*). Magnified 500 diam. Harmless in hayfever. An unusual form of pollen.

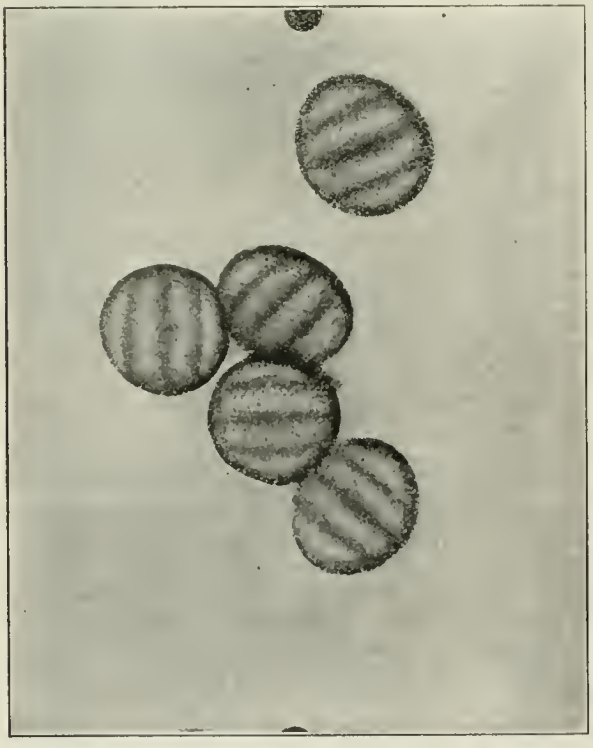

FIG. 12.—Pollen of flowering sage (*Salvia splendens*). Magnified 500 diam. Harmless in hayfever. Unusual on account of the number of lobes, three-lobed pollens being common (artemisias, etc.).

The *geographical distribution* of the plants is also given as furnishing a certain amount of assistance. An attack of hayfever in Pennsylvania can not be due to the mugweed (*Artemisia heterophylla*) as this plant, which we have found to be an important cause of hayfever on the Pacific Coast, is not found in Pennsylvania. The same principle applies to other plants in this list.

Every plant listed has been carefully tested for the hayfever reaction. With some of the plants, such as the ambrosias, gramineæ, artemisias, and chenopodium families, hundreds of tests have been made both in our Biological Laboratory and in making the differential diagnosis preliminary to immunizing patients against hayfever.

In the most important hayfever plants, such as the ragweeds (Ambrosias) and wormwoods (artemisias), the most common species have been listed. With most of the plants and trees, however, only a few of each genus are given, as we have found it a rule that the species of a family, in spite of considerable variation in size and general appearance, have pollens which are similar in their hayfever reactions.*

Many of these plants on this list have been sent to our Biological Laboratories for testing from all parts of the United States. The remainder have been collected in the course of regular inspections for hayfever plants by members of our Research and Botannical Departments. The list, which represents the most common plants in over 300 varieties examined during the past three years, has been of practical value in our hayfever work, and will, we hope, be of service to the medical profession.

AUDUBON BUILDING.

A CASE OF A BILATERAL CYSTIC DEGENERATION OF THE KIDNEYS.

BY LOUIS WENDER, M.D.,

COROZAL HOSPITAL, COROZAL, CANAL ZONE.

POLYCYSTIC disease of the kidney is a term accepted for that renal disorder which is characterized by the presence of multiple cysts of all sizes throughout the renal tissue. According to various authorities, this disorder is common at two periods of life; namely, before or after birth, or after the age of forty. Although many cases have been reported in the literature, this case is of special interest to warrant its publication, as it did not show any objective or subjective symptoms.

CASE.—A. W., admitted to St. Elizabeth's Hospital, Washington, D. C., on Dec. 19, 1912, suffering from auditory hallucinations and delusions of persecution. Physically he was in good condition. He stated that his grandparents died of paralysis (?). His mother died from a "numb chill" at the age of 48. His father was a victim of tuberculosis at the age of 44. One sister died at the age 23 from pneumonia.

The patient was born in 1865. He began his occupational career by farming, but later became a common laborer. He escaped the usual diseases of childhood, but had an attack of typhoid fever at the age of 17, which kept him in bed for about two months. Several years ago he was overcome by the heat. He admitted the excessive use of alcohol and stated that he was intoxicated on several occasions. He was married at an early age and had two children living and well. Five

died during infancy, cause unknown to him. His wife was living and well. He was admitted to the hospital with the following symptoms: Patient says that a society is against him and that they are preventing him from getting any work. This society had him locked up in jail and that they were anxious to take his life. He had to take extra precaution lest they poison him. Voices called him bad names.

During his entire sojourn in the hospital, which was about three years and nine months, he showed a slight change in his mental condition. The hallucinations and delusions became more quiescent. He was seclusive in his habits and asociable, and although he was in the ward with better class of patients he never entered into conversation with them. He read the newspapers and was well posted on current events. He never had any complaints to make and was contented with his environment. He helped with the ordinary ward work and went out walking daily in the company with the other patients.

Physical examination on admission to the hospital showed him to be well nourished; height, 5 feet 10½ inches; weight, 189 pounds. No stigmata of degeneration were in evidence apart from a left sided hydrocele. All the other organs were negative. Uranalysis showed a trace of albumin and hyaline casts. Wassermann reaction with the blood serum was negative.

He continued to be in good physical condition, never complaining of any pains or aches. He became very obese and at one time weighed as much as 236 pounds. He never complained and performed his duties in a satisfactory manner. He was found dead one morning by the nurse when the latter came to awake him at the

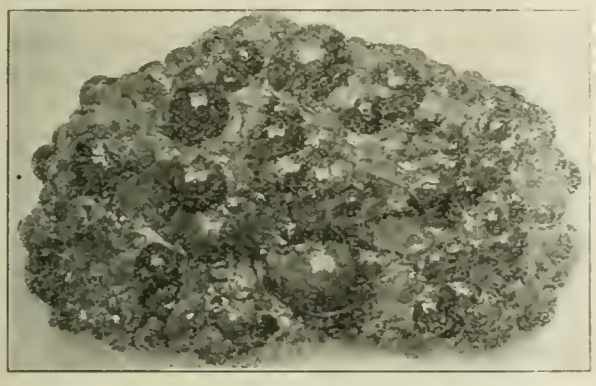

Fig. 1.—Right kidney; weight 360 grams; length 24 cm.

usual hour. A fellow patient stated that for the past few months A. W. had been suffering from asthmatic attacks during the night and that he would sit up on the edge of the bed to relieve the dyspnea.

Summary of autopsy findings: General examination showed a well developed and well nourished obese individual. Heart weighed 560 grams. The epicardial fat was increased and the pericardial sac contained a large quantity of serum and a blood clot. Both auricular walls were thin and flabby. The cavities were large. The right ventricle was large and its wall was thin and flabby. The left ventricular wall was thick and its cavity was spacious. The mitral and aortic leaflets were thickened and fatty deposits were found in the arch of the aorta. A longitudinal rupture was found at the base of the pulmonary veins, from which the blood escaped into the pericardial sac. The respiratory system was negative. The liver was large, weighing 1300 grams. The capsule was firm. Small cysts were found throughout the liver substance. The spleen weighed 200 grams. The pulp was soft and dark red in color. The right kidney (Fig. 1) weighed 360 grams and was about 25 cm. long. Cysts, as shown in the illustration, were found throughout the substance. The left kidney was in similar condition, weighing 420 grams (Fig. 2). A cross section of the right kidney shows the size of the cysts in the renal substance. (When the kidney was cut open after hardening it was found that the fluid had also hardened into a gelatinous mass in each one of the cysts, and before the kidney was photographed on one side the jellylike masses were picked out so as to show the depth of the cysts, this being the left side. The other side was left as it was cut, but from a few of the small cysts the material dropped out.) (Fig. 3) A left hydrocele was also present.

Comment: There are several theories concerning

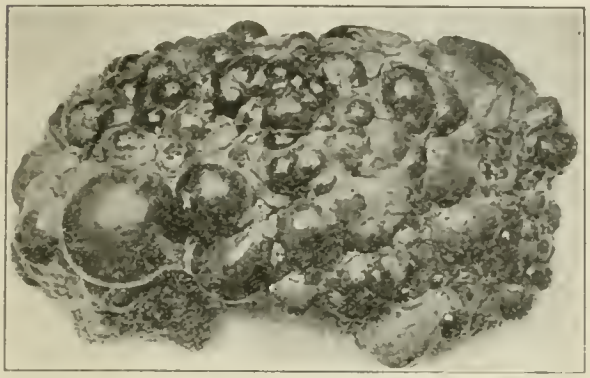

Fig. 2.—Left kidney; weight 420 grams; length 23 cm.

the etiology of cystic degeneration of the kidney. The one which is generally accepted is that of von Multach. He believes that cystic disease of the kidney is due to malformations of the organ in the course of its development. It has been shown that in one-fifth of all cases of cystic disease of the kidney, the liver and other organs are also affected with a similar disorder. In this case the liver and the left hydrocele seems to confirm the above assertion.

The symptoms of this disorder are not very marked during the early stage. At times during the course of an examination an irregular tumor is found at both flanks, the patient being unaware of its existence. However as the disease progresses, symptoms due to the presence of a tumor in the abdominal cavity make their appearance. The coexisting nephritis usually brings the patient to the physician. The renal secretion continues in spite of the degeneration of the structure. In this case on account of the deteriorated mental state, no sub-

Fig. 3.—Cross-section of right kidney.

jective symptoms were present. Albumin and casts were present, but the urinary secretion was present throughout his residence here. It would seem that the kidney can attain and undergo many changes without interfering with its functioning power.

The diagnosis is usually made at the operating table or at autopsy. Occasionally when the tumor is very large it can be palpated in the flanks. Uremic attacks are also present in some cases.

I wish to express my thanks to Dr. William A. White, superintendent of St. Elizabeth's Hospital, for permission to publish this case which occurred during my service at that hospital.

ON THE USE OF SMALL DOSES OF PITUITRIN FOR INDUCING AND SHORTENING LABOR AT TERM.

By ARTHUR STEIN, M.D., F.A.C.S.,

NEW YORK.

ADJ. VISITING GYNECOLOGIST HARLEM AND GERMAN HOSPITALS; FORMERLY ADJ. VISITING OBSTETRICIAN, HARLEM HOSPITAL,

AND

HENRY DOVER, M.D.,

OTTAWA, CANADA.

FORMERLY RESIDENT OBSTETRICIAN HARLEM HOSPITAL, NEW YORK.

THE mode of action of pituitrin, an extract of the posterior lobe of the cerebral hypophysis, has been the subject of much controversy in the recent obstetrical literature, and this is not surprising considering that much uncertainty still prevails in regard to the action and interaction of the secretions of the endocrinic glands in general. Imperfect knowledge of the powers of a given drug is apt to lead to more or less experimental and tentative administration, and the result in this particular instance has been manifested in the increasing reports of uterine rupture through the violent muscular contractions set up by the injudicious use and excessive doses of pituitrin.

It is precisely on account of these frequent accidents that we have entered upon a close clinical study of the effect of minute dosages, and our findings, as will be seen, are an ample vindication of the obstetrical virtues of pituitrin. A tendency to discrimination against the use of this efficient drug can be plainly traced to its abuse.

The fact is generally conceded that pituitrin, during the second stages of labor, usually retains the physiological character of the labor pains, although some observers believe that pituitrin labor pains are not equivalent to physiological pains, but that uterine tetanus follows, lasting two to three minutes, and even up to a quarter of an hour. According to the majority of those who have had experience with the drug, the labor pains induced by it have a normal rhythm, the uterine contractions are increased and gradually subside again. With special reference to the value of pituitrin as an adjuvant in normal labor, the diversity of opinions is such as to forbid even a condensed summary of the numerous contradictory reports in the literature.

Our own findings, based on experience with 64 cases during labor and 34 cases for induction of labor at term, are so essentially different from those recorded by other authors as to lead us to the publication and discussion of our pituitrin labor cases. We are well aware of the fact that to advocate the use of pituitrin in small doses early in normal labor at the beginning of dilatation, and especially for the induction of labor at term, a procedure suggested to us by Dr. S. W. Bandler, is to depart radically from the methods adopted by the pioneer workers in this field.

Upon the basis of our personal experience we are led to indorse:

(1) The use of pituitrin in far smaller doses than the customary ones. (2) The use of small dosages of pituitrin in the first stage of labor as well as later on. (3) The use of small dosages of pituitrin for the induction of labor at term.

Small Dosages of Pituitrin During Labor.—Our claims are based on personal observations in altogether sixty-four cases in which pituitrin in form of the Parke-Davis product was employed during the labors of forty primiparæ and twenty-four multiparæ. The pituitrin was always injected intramuscularly, as this was found to be a safe and highly efficient method of administration.

The usual dose consisted of two to three minims, far less than the smallest doses reported to our knowledge by most contributors to the obstetrical literature. A tacit agreement has apparently been arrived at among obstetricians making the contents of one ampoule, namely 1 c.c., the standard dosage for the acceleration of childbirth when the labor pains are sluggish and inefficient as the result of uterine inertia. Judging from the literature, ½ c.c. is almost the smallest amount in which obstetricians, both here and abroad, have been willing to place their confidence.

Aside from the question of dosage, the proper time for the administration of pituitrin has been referred with equal empiricism to the later stages of labor after the os has become more or less dilated and the presenting part has become engaged. In our close clinical observations the uterine contractions set up by minimal doses of pituitrin were of the normal, rhythmical, physiological type, with a gradual rise and fall in intensity.

Pituitrin in small doses during the first stage of normal labor.—Pituitrin is now generally recognized as an efficient adjuvant during the progress of labor, although there seems to be an unfounded prejudice against its administration at the onset of labor in the dilatation stage, a period when the drug rendered excellent service in our clinical experience. This prevailing opinion against the use of pituitrin during the early stages of labor is no doubt due to accidents from 1-c.c. doses. By the use of minimal doses we have been enabled to administer it with perfect safety during all the stages of the birth process.

A single three-drop dose proved sufficient, in our experience, for the production of efficient labor pains in about one-third of the total number of cases. Where pituitrin was repeated, the succeeding doses of 3 minims of pituitrin were usually given at half-hour intervals, the average number of small doses in each case being 1.78, with an average dose of 3 minims.

The duration of labor in the forty primiparæ under these small doses of pituitrin averaged fourteen hours, and in the twenty-four multiparæ eleven hours. In nineteen cases of this series where the cervix was fully dilated when the use of pituitrin was begun, the average duration of the second stage of labor was one hour and three minutes. It is

unnecessary to emphasize that this means a marked reduction in time of the expulsive stage.

No complications of any kind were noted in the 64 cases of this form of pituitrin administration. The mothers, without exception, did well under the use of pituitrin. Among the 64 infants there were but six stillbirths, and these were in no way referable to the minute doses of pituitrin, but the result of prolapsed cord and similar causes of fetal death.

In conformity with our own experience, a reduction of the large customary dose (1 c.c.) of pituitrin is recommended by Bandler, Schwartz, Bubis, Friedman, Norris, Druskin and others. Bandler, for instance, finds one-third of an ampoule of the Parke-Davis preparation an entirely sufficient dose in ordinary labor, subject to modifications according to special requirements in a given case. Norris points out that the usefulness of pituitrin would not be diminished and its dangers would be lessened, if it were dispensed in doses equivalent to half the customary ones. Small doses of pituitrin are credited by Friedman with a greater efficiency than large amounts for stimulating the activity of the uterine muscle. Bubis likewise indorses the use of small doses of pituitrin, and he also points out that the drug may be administered in any stage of normal labor, where it will shorten the birth process from two to twelve or more hours.

There is no reason, in the opinion of Bandler, why the use of pituitrin should be delayed until the second stage has been reached. These views are well borne out by our personal observations on the largest series of cases on record in which pituitrin in minute dosages has been employed as a routine medicinal agent in the management of ordinary labors. The freedom from complications and the shortening of the duration of labor certainly illustrate the efficiency of very small doses.

Pituitrin in small doses for the induction of labor at term.—The employment of intramuscular injections of small doses of pituitrin for the induction of labor at term constitutes the most interesting and important part of our observations. In the cases in which this treatment was adopted (34) it proved succcessful in one-half the entire number (17), contrary to the statements abundantly scattered through the obstetrical literature to the effect that pituitrin cannot be used to bring on labor before the os has at least begun to dilate. Numerous writers in this country and abroad assert the non-efficiency of pituitrin in the artificial induction of premature labor and abortion (which is also our opinion), as well as labor at term (a conclusion with which we are unable to agree.)

In view of the novelty of this plan of treatment, the method adopted at the Obstetrical Division of Harlem Hospital (Chief Dr. Brodhead), and also in private practice of one of us (Stein) is herewith given in detail:

At 7 A. M. the woman receives 1 ounce of castor oil, and two hours later, at 9 A. M., an intramuscular injection of 2 minims of pituitrin, followed at 11 A.M. by a repetition of this dose. If labor pains are elicited, the pituitrin is resumed at intervals of ½-1 hour; if no pains result, the treatment is stopped and another attempt is made on the third following day, again administering the same small dosage.

All the mothers in whom labor at term was induced by means of small doses of pituitrin did well, and the infants were invariably born in excellent condition.

In the successful cases, true labor pains usually began after the second small dose of pituitrin, sometimes after the first, or not until after the third dose. In a typical responsive case concerning a three para at term, labor pains began after the second dose. At half-hour intervals three other doses were given, making a total of four doses of altogether 9 minims. It agrees with the observations of others that in a certain number of normal parturient women—one-half our clinical material—absolutely no response to the administration of pituitrin for the induction of labor can be elicited.

The recommendation of pituitrin in small doses for the induction of labor at term without auxiliary measures of any kind is decidedly new. Together with the employment of mechanical means, in form of the bag, the use of pituitrin is indorsed for the induction of labor by Bandler, who finds that the repeated injection of pituitary extract often brings on or produces more marked labor pains when administered just as soon as discomfort and suggestive or actual pains begin after the introduction of the bag. In one of our own cases concerning a two para who was three or four weeks overdue, the introduction of the bag and bougie served as a supplementary measure to a single intramuscular injection of a 2-minim dose of pituitrin. The child was born in short order and in good condition.

Pituitary extract in form of infundin, a Burroughs-Welcome preparation, was used for the induction of labor at term by Blair Bell in England, but he employed the drug merely as a supplement to mechanical means. This combined treatment yielded excellent results in his experience, and the best method of inducing labor in ordinary circumstances is believed by him to consist in the combination of bougies and infundin, the drug serving to sensitize the uterus, which is the essential factor. It is recommended, therefore, first to sensitize the uterine muscle tissue with the extract so that the bougies may be better able to induce labor, during which the contractions are rendered more effective by the previously administered extract. Based upon a personal observation in a case which he thinks was the first occasion in which primary uterine inertia was recognized and treated before labor, he points out that this condition, if discovered before labor, may be dealt with efficiently through intramuscular injections of pituitary extract in preparation for the confinement.

Combined with other means, or independently, pituitrin was used six times to induce labor by Ingraham and Chase, who found it effectual in two cases with the rubber bag, and with slight manual dilatation in another. Once it was used alone, but without result. According to Sachs, the drug will act provided labor has already begun, but is incapable of eliciting labor pains, as it can act only by adding strength to the existing labor pains. There is, he claims, no sense in giving pituitrin before the work of delivery has commenced, the preliminary condition for its employment consisting in the presence of labor pains, meaning such

pains as have begun to open the birth passages.

The evidence contained in the literature as to the efficiency of pituitrin for the induction of labor is scanty, scattered and contradictory. The majority of writers seem to be agreed as to its uselessness for this purpose, namely, the arbitrary induction of labor, premature or at term. According to Quigley, for instance, pituitrin will not by itself induce premature labor or abortion (also our own view), but it is a valuable adjuvant to dilating bags or the cervical pack. We find that precisely in the scientific and judicious induction of normal labor at term, pituitrin, in very small physiological doses, has a remarkably fertile field of application.

We have endeavored to show that our personal findings, in a series of cases large enough to permit a reasonable estimate of the powers and limitations of pituitrin, are decidedly at variance with the great majority of statements in the literature not only for the indication of the drug in the induction of labor at term, but for its employment in extremely small quantities as compared to the customary dosage. Contributions to the subject of pituitrin in obstetrics are, in general, very numerous, and quotations from contemporaneous observers could be indefinitely extended, but this suffices to emphasize the prevailing lack of unanimity. Our own figures are strongly illustrative of the efficiency of pituitrin in very small doses, not only as an aid to the progress of parturition, but especially for the scientific and judicious induction of normal labor at term.

Equipped with this latest and best addition to the adjuvants at his disposal, the modern obstetrician will be enabled not only to hasten a tedious labor that has already begun, and more or less exhausted the patient's strength, but to select at his discretion and to the best interest of mother and child the most auspicious moment for the induction of labor.

Since the introduction of minimal pituitrin dosage in our service the number of forceps deliveries has been strikingly diminished. A comparative review of the total deliveries in twelve consecutive months at the Obstetrical Division of the Harlem Hospital (Chief, Dr. Brodhead) in 1915-1916, excluding the three months in which pituitrin was used, shows 1018 deliveries with 40 forceps operations or 3.9 per cent. In three consecutive months taken at random during 1914 prior to the introduction of pituitrin into the obstetrical service there occurred 166 births with 8 forceps deliveries or 4.8 per cent. The figure of forceps applications in three consecutive months when pituitrin in small doses was used is only 1.3 per cent. as compared to 3.9 per cent. in 1018 cases where pituitrin was not used at all or only occasionally in large doses (1 c.c.) at the end of the second stage.

This powerful drug given in the small doses recommended throughout this paper may be relied upon to lessen the number of forceps deliveries, thereby preventing the infliction of birth traumatism by the unskilled accoucheur. What is equally important, although not yet sufficiently recognized, all unnecessary moulding of the infantile skull in the maternal passages, in consequence of unduly protracted, unassisted, labor, will be avoided, thus guarding the infants against the dangers of brain injury and stunted mental development.

On account of their direct bearing on the recommendation of pituitrin as an adjuvant in childbirth, mention must still be made of two articles which have appeared since the completion of this paper. One of the writers, Wertenbaker, warns against the obstetrical use of the drug because of threatened rupture of the uterus following the employment of pituitrin. This warning rests essentially on the basis of a personal unfavorable experience limited to two cases. The amount administered in a single injection while not exceeding the customary dosage of one ampoule (1 c.c.) was very large as compared to our own method of administering pituitrin in small repeated doses.

Certainly the quantity of this powerful drug was enormous for the first patient, a negress of 44 years, with a pendulous relaxed abdomen, in her fourteenth labor, which had already lasted 24 hours when the injection was applied. Had pituitrin been given in small doses when the pains began, or better still, had this labor, which was delayed 18 days beyond the expected term, been induced by means of pituitrin alone or the bag and pituitrin, the outcome would in all probability have been very different.

In the second case also pituitrin was resorted to very late, namely on the day following the onset of the patient's fifth labor.

The figures compiled by Mundell from many sources do not afford a fair basis of comparison because of insufficient data in the individual reports. This observer still stands on the old ground that pituitrin practically always fails in the induction of labor and that "to give pituitary extract in the first stage of labor is bad obstetrics."

Our own experience does not suggest that pituitrin should be reserved for the so-called "ideal case" of a healthy multipara with a history of previous normal labors, and late in the second stage of labor. Perhaps the drug acts best *early in labor* before the chemical changes due to fatigue have altered the response of the uterine muscle to the physiologic stimulus of the glandular extract. Closer investigation of reported ruptures of the uterus under pituitrin (one rupture in about every 106 pituitrin cases, according to Mundell) will almost invariably show that the drug was given as a last resort often in excessive doses at the end of a protracted labor, or in other unsuitable cases (contracted pelves, etc.).

It cannot be overemphasized that the method which has yielded such excellent results at our hands, is beneficial because physiological, and can never result in muscular overstimulation with rupture of the uterus.

Conceding the vale of pituitrin for the mother, when administered in suitable cases and in small doses, Mundell fears the effects on the child and on the basis of a number of case reports describes them as undoubtedly bad in view of the high percentage of stillbirths and asphyxiated infants. This has not been our experience after the use of fractional doses. All of the children (with the exception of those that were dead before the drug was used) were born alive and in good condition after the routine employment of this drug in small doses,

either for the induction of labor at term, or for the acceleration of unduly protracted labor.

Our findings are in opposition to the statement that pituitrin should never be used in normal labor. When given with the discrimination that must govern the employment of all powerful drugs, pituitrin is a boon to both mother and child, whose interests are best served by the resourcefulness of the progressive obstetrician.

The novelty of our suggestions renders it advisable to emphasize our attitude toward pituitrin by condensing our findings in a brief summary as follows:

(1) The best mode of administration is by the intramuscular injection of an average dose of two to four minims.

(2) Pituitrin in small doses should be employed in labor at term exclusively, never for the induction of abortion or premature labor, where it would fail entirely.

(3) Pituitrin is indicated after the onset of labor for strengthening the uterine contractions; also in combination with castor oil for the induction of labor at full term.

(4) Pituitrin may be utilized as an efficient adjuvant to the bougie method.

(5) The judicious employment of these small, entirely harmless doses of pituitrin serves to reduce the need for the application of forceps, thus causing otherwise instrumental deliveries to terminate like normal progressive labors.

AURICULAR EDUCATION OF DEAF CHILDREN.

By JOHN DUTTON WRIGHT,

NEW YORK

PRINCIPAL OF THE WRIGHT ORAL SCHOOL FOR THE DEAF.

THE cooperation of physicians is needed in order that advantage may be taken of unrealized possibilities of educating slight powers of hearing remaining in the cases of many deaf children attending the special schools for the deaf throughout the country.

Since the intensity with which a sound affects the organ of hearing varies inversely as the square of the distance between the source of the sound and the ear, a child may be one hundred and forty-four times as deaf as a person who can hear ordinary conversation at a distance of one foot, and yet hear that conversation at a distance of one inch. If we speak with twice our ordinary loudness, the child may be two hundred and eighty-eight times as deaf and still hear what we say at a distance of an inch from his ear.

The distance at which speech is uttered under the conditions of ordinary daily intercourse preclude its being heard by such a child, and this explains why he grows up in utter ignorance even of the existence of language. Yet with proper auricular education, the brain of that child can be trained to associate ideas with spoken sounds; in other words. the child can be taught to hear and comprehend spoken language through the very imperfect organ of the ear.

I have had children seven years of age brought to me who were so deaf that, though of perfectly normal intelligence and living among educated people, they had reached that age not only without learning to speak but without understanding any spoken language or even having the conception of language. Within a few months, largely through the ear, I have taught them to speak many words and sentences and to understand them when spoken very near the ear. This has been accomplished by first awakening attention to sounds, then by patiently training the brain to associate ideas with certain groups of sounds which we call words. Gradually they learn that by giving attention to those sound impressions they can get something that is helpful and interesting. The idea dawns upon them that all objects and actions have certain

sounds that we associate with them which are their names.

Under the ordinary conditions of daily life very few and very imperfectly-defined sounds had reached them; so few and so indistinct that they could not attach meaning to them. By the simple process of uttering these sounds at sufficiently short range and with sufficient loudness to reach them *at the moment when we had awakened in their minds the ideas for which the sounds stood,* we trained their brains to comprehend language just as children with normal hearing gradually learn to comprehend it.

Our own understanding of language through hearing was arrived at by a long process of brain training. If we, with our normal hearing, were suddenly set down amidst a people who spoke a language which we had never heard before, we would understand nothing of what was said to us; not because we were deaf, but because our brains had not been trained to associate ideas with the sounds we heard. Slowly, day by day, as we heard the same sounds over and over again uttered at the moment when certain ideas were awakened in our minds, we should learn to associate those sounds with those ideas and the sounds would become words, and the groups of words sentences, and thus we should arrive at an understanding of the new language.

The small deaf child labors under some serious handicaps that we should not have in thus acquiring a new language. To begin with, he has no conception of what language is. We have already acquired one language. He has none. Then we hear the sounds distinctly and do not have to pay the close attention that he does in order to discriminate between sounds.

He has a somewhat retarded mental development, having missed the intellectual stimulus that comes with the acquisition of language and speech. It is difficult, therefore, to secure an adequate cooperation from the child, and this cooperation is essential in order to get the intensity of attention required to interpret imperfectly heard sounds. Perhaps you have yourself had the experience of trying to hear what was said to you over a telephone with a bad connection when the person speaking was using a language with which you were not entirely familiar. If so, you can then form some conception of the strain upon the attention of the listening deaf child. Ten minutes at a time is enough at the beginning, and until a considerable ability to comprehend has been attained.

During the past twenty-three years 35 per cent. of the pupils brought to my small private school have had sufficient residual hearing to benefit greatly by the form of auricular education we provide. I believe that an adequate examination of all the pupils in our special schools for the deaf would show that fully one-third of them, that is more than three thousand, are suitable subjects for such training of the brain through the normal channel of approach.

It is the easiest means of access to the language faculty of the child since it follows the line of normal development through millions of years. There are, of course, certain areas of the brain that can be reached in no other way and, therefore, a more symmetrical development can be obtained when any use can be made of the hearing.

It has been my experience that while artificial aids to the hearing may sometimes be useful in the earliest stage of awakening attention to sounds, and in the later stage in extending the range at which the hearing can be made of service, throughout the real educational process of teaching the brain to associate meaning with sounds and to remember those associations, the use of the unaided voice, applied directly to the ear, produces the best and most rapid results. Therefore, while I often use an acousticon to begin the work, and return to it when some considerable comprehension of spoken language has been attained, I do not use it in the intermediate educational process.

What should be our standard for the amount of hearing power that must be possessed by the deaf child to respond satisfactorily to educational auricular training? In the first place, such islands of hearing as remain must be located within the range of the speaking voice. Sometimes a child will respond to very high shrill sounds, such as a sharp, high-pitched bell or whistle, and yet be absolutely deaf to all sounds lying within the range of speech tones. In such cases, no satisfactory results can be attained in teaching the comprehension of language by the ear. Lip-reading and writing are alone available.

Having determined that the child has some power of perceiving tones within the range of the speaking voice, my own standard of amount is his ability to learn to distinguish between five unlike vowel sounds shouted an inch from his ear. I am willing to spend from two to six months of practice for ten minutes each day before definitely deciding that the brain cannot be reached educationally through the ear. If, at the end of that time, he cannot discriminate with 90 per cent. of accuracy, day after day, between five vowel sounds, or between five words of one syllable containing those sounds, I drop further effort along that line for a year. Then I make another, briefer test, and if the result is the same I again abandon the effort for another year. Each year I repeat my tests, as I have found in some instances that a power of sound perception, or at least of interpretation has appeared after a number of years of education by purely visual and tactile means. Then, too, the increased power of concentrated attention and the greater understanding of the importance of hearing that come with greater maturity are powerful aids in these auricular exercises.

The aid of physicians is much needed, both in detecting the existence of even very slight hearing power in the little deaf children of from four to ten years of age that they see and also in exerting their influence with parents and schools to secure the necessary auricular education for these deaf children.

Often the mere planting of the idea of possible auricular education in the minds of the parents by the physicians is enough to set the wheels in motion to accomplish it. But frequently he needs to use much effort to get the thing done. If all physicians, whether otologists or not, would lend a hand in disseminating this knowledge, many a deaf child would grow into a more normal man or woman than could possibly have been the case if no access had been found to the brain through the ear.

1 Mount Morris Park, West.

Medicolegal Notes.

Effect of Dismissal of Physician on His Liability.—In an action for malpractice the issue raised was whether the defendant was guilty of negligence which directly and approximately caused a gauze pack to remain in the abdominal cavity of the plaintiff's wife longer than it should have remained therein after an operation. The jury found for the defendant, and the plaintiff appealed from judgment for the defendant. The evidence showed that the defendant performed the operation in the usual way; that the insertion of the gauze pack was necessary; that several days after the operation the defendant attempted to remove the pack, but the removal created or again started a dangerous flow of blood, which, under such circumstances as shown by the testimony made it necessary to desist; that the plaintiff removed his wife from the defendant's sanitarium without the defendant's permission during his temporary absence. The defendant and the attendant physician and nurse all specifically testified to this fact, and further that the plaintiff was then informed that the pack had not been removed, because of which, and because of the presence of fever, it would be dangerous to remove the patient. The evidence further seemed uncontradicted that the physician who afterward attended the patient knew that the gauze had been placed in the wound and suspected its presence when the patient returned home, but relied wholly upon the assurance of plaintiff and his wife that it had been abstracted. That there was evidence in behalf of the plaintiff of contrary import could not alter the conclusion, since such evidence merely presented a conflict which it was the function of the jury to determine. Under such circumstances and under the findings of the jury, it was not the defendant's duty to follow the patient and be further liable for the due care of her wound. The court quoted Lawson v. Conaway, 37 W. Va. 159, as follows: "All of the authorities admit that the patient may at any time discharge or dismiss his physician, and from that moment such physician is relieved from responsibility. It would be very strange if the law were otherwise."—Miles v. Harris, Texas Court of Civil Appeals, 194 S. W. 839.

Administering Anesthetics Not Practicing Medicine.—Ky. St. Section 2613, makes it unlawful for any person to practise medicine in any of its branches in the State who has not registered a certificate of the State board of health authorizing him to engage in the practice. Section 2615, subsection 5, provides for the examination by the State board of health of any other persons applying for authority to treat the sick or injured or in any way discharge the duties usually performed by physicians, and that the term "practice of medicine" shall not include trained or other nurses, etc. Section 2618 provides that to announce to the public in any way a readiness to treat the sick and afflicted shall be deemed to be engaging in the "practice of medicine." A duly licensed and trained nurse was employed to administer anesthetics by a duly licensed surgeon under his direction, and the administering in each case was done by her under his personal direction and supervision. In an action by the State board of health against the surgeon and the nurse for violation of the statute, on an agreed statement of facts, it was held that in the performance of such services the nurse was not engaged in the "practice of medicine" within the statute.

The evidence disclosed a variety of opinions as to whether women or men make the most safe and efficient anesthetists, or whether trained nurses educated for the purpose or licensed physicians are most competent for the work of administering anesthetics to patients undergoing surgical operations. Some of the opinions were to the effect that the work of an anesthetist is most responsible, and that upon his or her competency and efficiency depends in some measure the safety of the patient, while others seemed to hold to the opinion that the administering of the anesthetic is attended with little danger to the patient if the surgeon has properly performed his studies in the examination of the patient beforehand to discover his physical condition and whether there is any reason existing why a certain anesthetic should not be administered, and to what extent and in what quantity it should be administered, and thus equip himself to be able to give the necessary directions to the anesthetist. There was not any contention that a nurse trained for the purpose is not thoroughly competent for such duties, or that the nurse in question was not qualified for the work, and both sides agreed that one to administer anesthetics safely and efficiently must have training and experience for such purpose in order to be efficient and competent for the service whether the anesthetist is a licensed physician or a trained nurse. Some of the opinions were to the effect that the licensed physicians, taken as an entire body, contain a very large number of members who are not qualified for such duties, never having made a special study of it and being without experience. The court held, however, that these differences of opinion were questions for discussion and investigation by the members of the medical profession, and the only question it could determine was whether the nurse was engaged in the practice of medicine within the statute; and this it determined in the negative.—Frank v. South, Kentucky Court of Appeals, 194 S. W. 375.

Prescriptions of Intoxicating Liquors.—South Dakota Laws 1905, Chapter 123, Section 1, provides that it shall be unlawful for any physician to furnish a prescription for any kind of intoxicating liquors to be used as a beverage for any purpose except for medicinal purposes in case of actual sickness. It is held that this section applies only to cases where the application for the prescription is made by some one other than the person alleged to be ill. Section 2 makes it unlawful for any physician to furnish any person a prescription for any kind of intoxicating liquors except to patients of such physician, where the patient is afflicted with some disease and his condition is such that in the opinion of the physician the taking of intoxicating liquors would be beneficial. It is held that this section applies where a person himself seeks the advice of the physician and states his ailments, and such person is a "patient" within the meaning of the act. In a prosecution of a physician under such acts the essence is whether or not the physician acted in good faith in giving the prescription to his patient.—State v. Morton, South Dakota Supreme Court, 162 N. W. 155.

Expulsion from Medical Society—Resort to Courts.—When parties form voluntary associations, such as medical associations, and adopt rules by which to regulate their conduct and measure their rights, and by the provisions of which members may be admitted and expelled, such rules are articles of agreement to which all who have become members are parties and must be governed thereby in their relations to such associations. The decision of the association in admitting members and in disciplining, suspending, or expelling them, is of a quasi public character, and in such cases the courts never interfere except to ascertain whether or not the proceeding was pursuant to the rules and laws of the society, whether or not it was in good faith, and whether or not there was anything in it in violation of the laws of the land. In other respects the sentence of the society is conculsive like that of a judicial tribunal. Where an association under its rules expels a member, such member must resort to and exhaust the remedies provided by the association itself, through its constitution and bylaws, before applying to a court of equity for relief. But where a member has been expelled in violation of the rules and bylaws of the association, and the bylaws do not allow adequate relief by appeal from such expulsion, the member may resort to a court of equity for relief.

A member of a county medical association, in an action for an injunction to restrain his compulsion, alleged that he had been tried by the association upon charges presented on the night on which he was tried and convicted, he having had no notice or knowledge of the existence of such charges until after he had presented his defense to other charges of which he had notice; that his trial was in violation of the bylaws and rules of the association, while the provisions for appeal made by the association were wholly inapplicable and inadequate, and could not have afforded the plaintiff any relief for his alleged unlawful conviction and expulsion. It was held that he had a right to resort to a court of equity for relief.—Brown v. Harris County Medical Soc., Texas Court of Civil Appeals, 194 S. W. 1179.

Military Medicine.

A DAY'S WORK.

"THE United States Army must have 24,000 physicians." These words bring to our minds a realization of the significant part that is to be played in the Great War by the Medical Profession of the United States. Within the next year the medical service of the army will require the service of 144,000 men, of whom 24,000 must be trained physicians. Approximately two out of every nine physicians of military age, 22 to 55 years, throughout the United States and its possessions will be taken to raise the number to the necessary total. Five thousand commissioned medical officers are already in the Reserve Corps and every effort is being made to obtain the remaining number of physicians between now and October 1.

For the American doctors who are to be called from the comparative quiet of their practice and are to be whirled into the midst of the great European cataclysm, Andrew Macphail's description in the *Lancet* of June 30, of the taking of Vimy Ridge and the doctor's part in it, helps to a visualization of a day's work at the front.

"It is difficult," he says, "for you to appreciate how small is the battle area occupied by a division. It is measured in that case (cited) 2000 yards in depth with a frontage of 1000 yards—about the size of a nice farm. This area was approached only by night or in fog, though ambulances and persons singly on foot might take a chance. Once the area is entered all life is underground.

"Regimental aid posts and field ambulance relay posts were parts of a system which ended at the rear of the battle area where a huge advanced dressing station was partly excavated and partly built. Two tram lines had been thrust up by night on either flank . . . and were of great service in bringing casualties down. . . .

"Let us now attempt to follow the progress of a wounded man. When he falls he is attended by the regimental medical orderlies and is sent back a few hundred yards by regimental bearers to the aid post, where he is more carefully dressed by the regimental medical officer. There he is handed over to the field ambulance bearers and borne by hand, by wheeled stretcher, or by trolley from one relay post to another until, finally, at a distance of one or two miles he arrives at the advanced dressing station. There the dressings are examined and, if necessary, renewed. Trains of trolleys drawn by gasoline engines are in waiting to bear the loads farther to the rear, where the motor ambulance convoy waits, which takes them to the main dressing station. Here the cases are redressed and so sent on to railhead, clean, warm, and fed."

"Of the wounded in detail one sees little; one sees them in the mass. Our business is to speed them on their way, and 12 surgeons in a dressing station, working night and day, will clear the casualties as fast as they come in. The walking classes went direct from the field to collecting points and were sent down in 'buses, forty at a load. The lying cases neither move, nor speak, nor utter a sound. It is only when we get to the base or come to England that we see the wreck of war and the pity of it all. . . .

"Sixteen battalions were engaged on this 1000-yard front, 16 men to a yard. Each one had its piece to do, and when done another battalion passed through and took up the advance. All winter the performance had been rehearsed behind the lines on a terrain marked off with tapes to imitate the battle area as discovered by aerial photographs. To each battalion was allotted a certain number of minutes for its task. All was over by 2 o'clock, and before darkness fell the field was clear. The evacuation from the front was so perfect and rapid that cases began to accumulate at the advanced dressing station; and there they lay, a piteous spectacle, but their presence was the finest tribute ever paid to the medical service. A general passed by, and when he saw the wounded lying in ranks on each side of the road covered with snow, he thought the medical service had broken down, until it was explained to him that all casualties were dressed and fed, eased with morphine, and covered with blankets, instead of lying where they fell. Additional convoy was procured and by midnight all were in their beds. That day's work was over."

TRACHOMA AND ARMY RECRUITS.

THE examination of army recruits is a matter of grave responsibility. The examining medical officer must be possessed of much diagnostic perspicacity, or he may be the indirect means of spreading disease and impairing the fighting efficiency of an army. For instance, trachoma is a common eye affection, in a high degree contagious, and if not detected in time may be responsible for the invaliding or even blinding of hundreds of soldiers. Surgeon John McMullen, U. S. Public Health Service, points out in *Public Health Reports*, July 13, 1917, that during every recent war trachoma has been one of the greatest menaces to the health of armies. The malady, he says, is extremely frequent in this country, and is most extensively found among the Syrian, Armenian, Hebrew, Italian, Polish, and Greek races. It is common among the Indians, and on some of the reservations, McMullen says, 90 per cent. of the inhabitants suffer from trachoma. It is widely distributed throughout this country. Diagnosis is often difficult, since, as the causal organism is unknown, it is still based on clinical evidence. Trachoma is transmitted from the sick to the well by the secretion which is conveyed to the healthy eye by means of such infected articles as towels, handkerchiefs, bed linen, etc. Trachoma is essentially a chronic disease, and, untreated, lasts, as a rule, for the greater part of a lifetime. It frequently exists in a latent or dormant stage, and on this account there is grave danger that recruits may be enlisted suffering from this disease, unless the greatest care is exercised.

The eyelids of all recruits and drafted men should always be everted, the examination to include the retrotarsal fold, and the conditions of the membrane should be noted in a space on the blank form reserved for this purpose. If the conjunctival surface of the eyelids is not smooth and pink, if there

is any redness or secretion, especially in the retrotarsal fold, such cases should be segregated for examination by those trained in the diagnosis of trachoma. An applicant who is found to be suffering from a well-marked trachoma should not be immediately rejected, but should be given treatment and his trachoma cured. He can then be again examined to determine whether he has resulting visual defects sufficient to cause his rejection. In this way a case of dangerous contagious disease will be eliminated, and probably a good soldier gained.

LETTERS FROM AN M. M. R. C.

A Training Camp Somewhere in The United States.

The medical man who has been ordered into active service or is about to join one of the numerous governmental training camps for officers of the U. S. A., should prepare himself for many disillusions. His enthusiasm will undergo some tremendous slumps. There are certain prescribed rules and regulations (of which he is quite ignorant) that have to be carried out to the letter or trouble intervenes. He will probably travel in his new uniform and will have certain titillating surprises by having every soldier he passes salute him. An officer is not supposed to burden his hand carrying luggage, so his right hand which is the only one he may salute by, is quite free. This is quite the reverse of many privates whom he will find at every turn and corner of the street and railroad station. One must not be sentimentally sorry for these privates. They have probably just learned how to salute and are only too keen for the opportunity to try it out. If you decide to travel in civilian costume you are breaking one of the laws of the service. On active duty an officer is not permitted even to have a civilian's dress in his immediate possession. It is forbidden any officer to be in any public place in company with anyone who is drinking anything stronger than water no matter what mild beverage he, the officer, might indulge in. On the streets of strange cities he will have odd experience with strangers—mostly girls, coming up and wishing Godspeed. If of a naturally retiring disposition he will likely become most embarrassed.

A training camp is all that the name implies. You would not expect the niceties of Windsor Castle at Muldoon's.

Your first mental shock will come on your arrival at destination. Officialdom has a particular faculty for picking out the most impossible sites for establishing training camps. Would they choose a nice golf course with rolling meadow and green turf, with a river nearby clean enough for the tired and sweaty soldier to bathe in? Perish the thought! If the place is alive with bugs, hot as Hades, with a nice sticky clay soil surface when it rains, infested with flies, ticks, jiggers, and mosquitos, it becomes at once a desirable spot in governmental eyes for the establishment of a camp. Of course day laborers are so tender that they can not begin to stand what the ordinary soldier or doctor can! That's why they so often quit while construction is in progress. When the government tells you that you are to go in training it means it with a sincerity past human belief.

On your arrival at the station you will seek in vain for anyone to carry your hand luggage. You will find yourself alone amidst teamsters, expressmen, contractors, sub-contractors, and others who are trying to sell their line of goods to the Government. No one is in uniform except yourself and apparently you have no place to go and no one wants you. Of what use is it to you at this particular juncture having accepted a commission of major to uphold the honor of your country? Your printed governmental instructions tell you that when ordered to a station on active duty, on arrival you must present yourself to the adjutant and show him your credentials. Depositing your luggage in any old place you ask to be shown the way to his quarters. You are told it is one of the houses on the parade grounds and you follow the road that leads in this direction. It is a long way off! There are no taxis or other conveniences around, so you have to foot it. As you near your destination the midsummer tropical heat beating down on the high collared, closely buttoned heavy khaki uniform, the leather puttees, and regimental cap, produce a state of perspiration that would defy a Russian bath towel to mop up. It streams down in rivulets from the band of your cap till it sinks absorbingly in your collar and ever increasing on, down and down. To add to the discomfort, soldiers are getting as thick as flies and you are constantly returning salutes. This prevents you using your saturated handkerchief with any degree of satisfaction. At last you have arrived and now await your turn among the many who have business with the Adjutant.

It is now you realize in full force what a bee hive the center of the fort is like. You look out of the window and take notice of the pretty houses of the officers of the regiment with gay colored flower beds indenting the cool green lawns in front. You wonder in which house you will be given quarters. Your book of governmental instructions tells you that even second lieutenants are provided with three rooms and if their furniture has not as yet arrived the quartermaster will furnish you with whatever you need. From beyond the compound of the parade grounds, seem to stretch miles and miles of tan colored tents. Ambulance motors, prairie schooners drawn by mules, express wagons, vans of butcher supplies, and other like, congest the road that leads to the stretching land of tentdom. You speculate on the enormity of the proposition of having to feed and house thousands of men. These musings are interrupted when you find it is your turn to see the adjutant. You introduce yourself by your full military title when you are at last face to face and as it seems to make no visible impression somewhat hesitatingly you produce your orders. He looks the document over in rather a bored manner and icily tells you to go to the adjutant of the training camp which someone will direct you to. With a nod of dismissal you leave the office (probably with your hat hindside before, this oversight being most politely brought to your attention by a passing sergeant); your feelings of pride and enthusiasm have now oozed to the lowest ebb. There is none of the sensation, the thrill, that you experienced when you first put your uniform on to show to the family at home and your native village at large.

A friendly face that salutes you gives you courage to ask the direction to the officers' training camp of the medical reserve. It's a long way off! Yes, over a mile! Not quite two! It's the furthest line of tents and shacks in the direction pointed.

As the major walks in the broiling sun he looks longingly at the railroad station and a train just pulling out. He crushes the thoughts that leap uppermost. The adjutant's quarters of the training camp is found located in a wooden shack recently constructed, surrounded by more tents and more rough hewn shacks. To reach this point you have traveled by foot the deeply pitted road, dodging in and out between the drays, ambulances, and motors bumping by on army business. This adjutant is more friendly and when you introduce yourself as Major So and So, he says, "I am glad to meet you, *doctor!* The secretary will fill out your card and will then direct you to the way to Captain Smith's quarters, who will inform you what is required of you."

The Sanitary Service of a Battalion During an Offensive Campaign.—According to Cheyrou in *Le Caducée* for June 15 it was expected before the latest French offensive that much would have been learned from the Somme campaign in 1916. As a matter of fact, but little difference was to be noted, although there was some improvement in the rapid evacuation of wounded to the rear. The commander of the batallian informed the author before the offensive of the point of departure of the attacking waves so that the site of the *poste de secours* could be appropriately chosen. An excavation was prepared and roofed in with planking and sheet iron, the work being done by the stretcher men. This shell proof room was furnished with a bench, table, shelves, etc. On the morning of the day of attack the author was at his post with some musicians, who acted as emergency stretcher men. Soon the regular stretcher men arrived with supplies, which included socalled compass stretchers, small vehicles for transporting stretchers, dressings and Vincent's powder. Just before the attack, in the evening, the soldiers were accompanied in their march by orderlies with first aid dressings. The auxiliary physician now gave the word for the stretcher men to advance with the troops. The author remained at the dressing post, his task being to relay the wounded to a central *poste de secours* in the rear. The auxiliary who accompanied his stretcher men was to distribute them as he saw fit. The author, at his post, was accompanied by musician stretcher men, who were to relay wounded after they had been dressed. A ranking orderly registered the wounded as they arrived and made out the attests. A second subordinate with motorcycle kept the chief batallion physician in the rear closely informed as to the need of fresh men and supplies. Those but slightly wounded at the front were guided by orderlies to the *poste de secours*, having received no first aid dressings. After their wounds had been dressed they were directed to the rear by the relay men. All of the other wounded received first aid treatment on the spot in the most sheltered places and the stretcher men, informed as to their whereabouts, bore them to the first *poste de secours*.

After the troops had advanced well beyond the first post the auxiliary physician saw to it that an advanced post was established in a natural or artificial shelter. The author's original post now functioned in part as a base. With the further advance of the troops others were established, while messengers, by a system of reports, kept the new posts supplied with stretches, relay men, dressings, etc.

The author acted as middle man between the auxiliary physician at the front and the chief battalion physician at the rear. To protect the wounded and stretcher men as much as possible a trench was cut from the *poste de secours* forward and the stretcher men traveled along certain definite lines, which culminated in the socalled ravine. Some of this work was done in advance of the battle, but when new posts were needed the excavation must have been impromptu. Apparently certain first treatment was given after entrance into the trench. Some stretchers were carried, others transported in wagonettes; as a rule the wounded remained in the stretchers, but were carried onward by relay men.

In an offensive those wounded by machine gun bullets show a marked preponderance. Shell fragment wounds are correspondingly rare. Machine gun fire may be so deadly as to cause wide havoc.

In wounds of the head and chest tincture of iodine was sprayed on; in wounds of the abdomen ether is preferred and for wounds of the extremities Vincent's powder. The rule is never to explore a wound at a dressing post nor to touch one with the fingers. Nevertheless every attempt is made to secure thorough disinfection by means of irrigation and insufflation. Fractured limbs and injured abdomens are immobilized. Those wounded in the thorax receive morphine. In shocked subjects oil of camphor is injected and the patient is allowed water, with or without rum. Much pains have been taken to mitigate the severity of transport. Wagonettes for stretchers are provided with springs and rubber tires. Coverlets are available for the wounded. Ambulance autos come up as near the front as is safe. If possible there is no change from one stretcher to another.

The Successful Conservative Treatment of Early Gas Gangrene in Limbs by the Resection of Infected Muscles.—C. H. S. Frankau, Hamilton Drummond, and G. E. Neligan report their method of treatment of gas gangrene which is carried out along the lines laid down by Cuthbert Wallace in an article in the *British Medical Journal*, September 16, 1916. Wallace made the following points: (1) It is rare to meet gas gangrene without muscle injury. (2) It is chiefly a disease of muscles, and is rarely dangerous unless muscle is involved. (3) The lesion in its early stages may be described as a longitudinal one, running up and down the wounded muscles from the seat of the lesion. Muscles, or groups of muscles, are involved, while others escape. (3) It is rare to find all the muscles of a segment of a limb involved, save in a segment distal to one in which the main blood supply has been cut off. Thus the whole leg dies and becomes gaseous when the femoral artery has been blocked in the thigh. (5) There is little tendency for the infection to pass from one muscle to another. This is well shown in amputation stumps, where one muscle dies and becomes gaseous, while the rest of the cut muscles remain healthy.

From observations made in clearing stations over a period ranging up to twenty-one months, these surgeons agree with the above facts. In no case did they find gas gangrene commencing as a subcutaneous infection; injured muscle is in all cases the initial focus, the appearance of crackling in the subcutaneous tissues being a secondary phenomenon, due to extravasation of gas from the infected muscles below. In view of this, they planned their treatment on the following lines as soon as the diagnosis was made: To explore the primary focus with a view to attempting to arrest the infection in the muscle, or group of muscles, involved by resection of the infected areas. Such a resection may involve a part or whole of single muscles, or groups of muscles.

Resection should be limited to cases in which the main vessel of the limb is intact, and should be replaced by amputation where the operation must be to extensive as to be likely to give a limb which would be of less value than an artificial limb. Extensive resections, however, may be performed regardless of the ultimate utility of the limb as a life-saving operation, it having been quite clear in some of the cases that an amputation, or a further amputation could not have been carried out without grave risk of life. Resection should extend until muscle is reached which has the following characteristics: (1) The color is unchanged. (2) The contractility is normal. (3) A good blood supply is present, as indicated by free bleeding from the cut surface. Experience has shown that even if such muscles are, as they may be, slightly infected, free drainage and an open wound will arrest further development of the condition.

The treatment of cases after resection is carried out on the following plan: The dressings are reduced to the absolute minimum—that is, one or two layers of gauze only are placed over the wound so as to allow free access of air, and, if possible, sunshine to the wound region; constant of intermittent irrigation of the wound by some modification of the Carrel method—eusol, saline, or hydrogen peroxide being used as the irrigating fluid.

In connection with the cases cited in the report the point must be specially emphasized that gas gangrene had already developed in some patients, though they were admitted a very short time after being wounded. In fact, in units at the front established gas gangrene has to be treated *ab initio*, in addition to gas gangrene developing at a later stage.

One case illustrative of the treatment is as follows: Lieut. F., wounded 4 p. m. on November 2, 1916, by rifle grenade fragment; admitted at 7.15 p. m. same day—three and a quarter hours after being wounded. While admitted as a walking case, he was very ill; pulse 120, of poor quality and irregular; tongue furred, and features pinched and worn. There was an irregular wound the size of a threepenny-piece (about 1.6 c.m. in diameter) on the posterior aspect of the right arm just above the internal condyle of the humerus; there was no exit. The whole upper arm appeared swollen; crepitus was present and gave a tympanitic note on percussion. The crackling was most marked on the inner aspect of the arm and extended as high as the anterior axillary fold above in front, but to not quite so high a level behind. He was given a general anesthetic at 8 p. m. The wound entry was first excised; much damage to the triceps was found locally, and the projectile could be felt to the inner side of the vessels in the front of the arm at the junction of the lower and middle thirds; a second incision was made over this and the biceps muscle showed evidence of gas infection. A further incision was made along the length of this muscle from origin to attachment; some bruising of the inner border of the muscle at the situation of the projectile, discoloration of the inner half of the muscle, varying from a dull red color at either end to a deep plum color in the center was found. Over this discolored area bubbles of gas were present under the fascia covering the muscle. This half of the muscle did not respond to tap stimulation, whereas the normal half responded sharply. The inner half of the muscle was resected in its entirety.

A tube drain was inserted into the posterior wound; anterior wounds were left open, small tubes being inserted and continuous eusol irrigation began immediately after completion of the operation. The pulse dropped to 88 six hours later and never rose again. Wounds remained clean without pus formation and were closed by secondary suture with discontinuance of irrigation on November 9. By November 17, wounds practically healed and patient evacuated to base with fair power in his arm and remaining portion of biceps could be felt contracting. Pathological report gave presence of an anaerobic gas-forming organism in infected tissue, with hyaline degeneration of groups of fibres with separation. This condition represents a very early stage in the process of gas gangrene. Long bacilli could be recognized between the muscle fibres, but they were very scanty.

This case showed the extreme rapidity of the spread of this infection, and if treatment had not instituted so early, the patient would in all probability have lost his life owing to the virulence of the infection. The resection of half the muscle rather than the whole was due to the longitudinal spread of the infection along the length of the fibres. The transverse spread is a late manifestation of the advanced stages of the condition.—*British Medical Journal*, June 2, 1917.

Military Hospitals Planned.—Announcement has been made in Washington that thirty-two new army hospitals are being built at a cost of $14,500,000 for National Troops' and National Guards' camps. Plans have been made for enlarging some of the thirty hospitals used in connection with the officers' training camps. Two general hospitals at ports are being taken over by the army and a number of general hospitals are being taken over or built for special treatment work. Steps are being taken to work out plans for reconstruction hospitals where artificial limbs will be made and fitted, repair surgery done, and the re-education of cripples begun to enable them to use the artificial limbs. The aim of the medical department is to have hospital provisions for 5 per cent. of the enlisted force by fall and to then extend that to 10 per cent. Abroad facilities for 20 per cent. of the expeditionary force will be provided for. Provisions will be made at the cantonments in this country for 3 per cent. of

the troops in each camp. The hospitals constructed at each of these camps will contain at the fewest 1000 beds and the cost of each hospital will be approximately $500,000. Each of these hospitals will have an equipment equivalent to that of the best hospitals in this country. Each man in the new armies will have the equivalent of six or more examinations by specialists, in addition to the examination as to his general health and condition.

Troops at Forts Adams and Greble Quarantined.—Owing to the prevalence of diphtheria in Newport, Jamestown, and Portsmouth, troops at Forts Adams and Greble have been placed under quarantine. Orders have been posted warning the men to refrain from eating ice-cream because of the discoveries made at a farm in Portsmouth from which came the cream for at least two of the manufacturers of ice-cream.

Would Not Draft Hospital Employees.—At the recent annual meeting of the American Psychological Association in New York, a committee was appointed to take up the matter of getting the employees of hospitals for the care of the mentally disordered exempted from conscription. This organization expressed the opinion that these employees are rendering such a significant service to society that drafting them for the army would be a misfortune. The members of this committee are Dr. William A. White of the Government Hospital for the Insane at Washington, D. C., Dr. Franwood E. Williams of the National Committee for Mental Hygiene, and Dr. L. Vernon Briggs of Boston, Mass.

Examinations for Regular Corps of Army and Navy.—The National Board of Medical Examiners announces that at the examination held in Washington, June 13 to 21, there were 24 qualified candidates, 12 of whom appeared for examination, the others having been ordered to active duty between the time of their application and the date of the examination. Of the 12 who took the examination 9 passed. The next examination will be held in Chicago, October 10 to 18. There will also be an examination held in New York in the early part of December. The regular Corps of the Army and Navy may be entered by successful candidates, without further professional examination, providing they meet the adaptability and physical requirements.

Army Wants Free Doctors.—The Surgeon General of the Army has sent out the following message to various hospitals: "The office of the Surgeon General of the Army is being put to much inconvenience by the fact that many physicians of the staffs of hospitals are accepting commissions, although they cannot be spared for military duty. The Surgeon General does not wish to commission those who cannot respond to service when called. While it is imperative that as many men as possible be made available for the service, those members of hospital staffs who cannot be spared are requested not to apply for or accept commissions unless they intend to respond to any order for service which may be received."

X-Ray Tests for the National Guard.—The Sixty-ninth Regiment, New York, has been subjected to the *x*-ray examination for tuberculosis. Of the first 600 plates examined only 22, a fraction more than 3 per cent., were found to have tuberculosis sufficient to disqualify them for military service. In addition there were 18 who showed old lesions or lung changes, indicating arrested tuberculosis.

Petition for Selective Draft for Doctors.—A petition asking Congress to provide for a selective draft for doctors for military service and pleading for the exemption of bona fide medical men from the provisions of the present draft law has been sent to the various New York City Hospitals to be signed by the physicians practising there. The draft proposed would take men between the ages of 21 and 45 and would be carried out similarly to the draft for the army. It is said that the petition was sent by the Council of National Defense at Washington. The reasons given for suggesting this plan are that the volunteer system of recruiting has failed to secure the required number of physicians desirable for active army service and has failed to exclude physicians whose services at home are essential to the public welfare in health departments, hospitals, medical colleges, and isolated communities. Announcement has been made at Washington that 24,000 physicians will be needed for war service and that 12,000 of these must be obtained by October 1. There are in the United States approximately 90,000 physicians of military age—from 22 to 55 years—so that to obtain 24,000 will mean that about one of every four physicians must be enlisted.

John F. Harris has been elected chairman of the New York County Chapter of the American Red Cross. He succeeds Harvey D. Gibson, and will serve without pay as did Mr. Gibson.

Lieut. Linsly R. Williams, M. R. C., formerly Deputy Commissioner of Health of New York State, who has recently returned from France and England, where he made an investigation of the health and sanitary conditions of both the military and civil populations for the National Research Council, has gone to Washington to take an assignment in the office of the Surgeon General.

American Women's Hospitals.—The War Service Committee of the Medical Women's National Association has organized the American Women's Hospitals for work at home and abroad. The Surgeon-General of the Army and the General Director of the Department of Military Relief of the American Red Cross, have approved the provision made for service to the Army and to the civil population. The work will be officially part of the medical and surgical service of the American Red Cross. The scope of the plan is a broad one. It includes units for maternity service and village practice in the devastated parts of the Allies' countries, and hospitals run by women for service there as well as for the United States Army in Europe. In this country, acute and convalescent cases will be treated in hospitals equipped for the purpose; soldiers' dependents will be cared for, interned alien enemies will be given medical aid, and substitutes will be provided to look after the hospital service and the private practice of physicians who have gone to the front. The first units hope to go to France and to Serbia in the early fall. Headquarters have been established at 637 Madison Avenue, New York City. Dr. Rosalie Slaughter Morton is Chairman of the War Service Committee.

THE FUTURE OF THE CRIPPLED SOLDIER.

AMONG the many problems which we shall have to face in connection with our share in the great war there are few, if any, which exceed in importance the question of what to do with the war cripples. The facile, obvious solution to the problem, namely, that they should be pensioned off for the rest of their lives is, like so many obvious things, a poor solution. In the first place, pension disbursements which would be at all adequate would be a tremendous burden on the nation—one, indeed, which it could scarcely bear, superimposed upon the gigantic actual cost of the war. In the second place, such a procedure would be extremely unfortunate for the men themselves. It is a mistaken kindness to make a pauper of a man. These patriots, crippled in the defense of their country, should not have their moral fiber destroyed by accustoming them to accept charity. Let us then "find a w'y," as Sentimental Tommy would say. Let us see how our Allies have approached the problem.

In Paris, from May 8 to 12, there was held a meeting of the *Conférence Interalliée pour L'Etude de la Rééducation Professionnelle et des Questions qui Interessent les Invalides de la Guerre.* This society of the formidable name was well attended by large employers of labor, by lawyers, and doctors, and by many disabled soldiers themselves. Six main sections were formed, each of which discussed one particular feature of the subject. These six aspects were as follows: First, physical re-education; second, the question whether doctors or instructors should have main charge of these cases; third, the placing of the disabled in civil life; fourth, the economic and social interests of the disabled; fifth, the blind, deaf, and nervous cases; sixth, the documentation and propaganda of matters relating to the disabled.

The first section discussed reeducation from the standpoint of physiotherapy, artificial apparatuses, and work. The second section disclosed a considerable difference of opinion as to whether the doctor or the instructor should have charge of the work of rehabilitation, although the final verdict seemed to be that the doctor should advise from his professional examination of the patient, while the instructor should actually carry out the work. The third section found considerable difference in the problems according as it was contemplated placing the charges in England or in France. Although the latter country has a much greater quota of cripples, the problem of placing them in civil life has been thought out much more completely in England. Section four voted that workshops be established in the Allied countries similar to those in England, that is, workshops especially adapted to men who cannot compete with the perfectly sound workman. Section five directed its energies to devising schemes to keep together the families of the blind soldiers; in other words, to avoid the fault of those institutions for the blind where only the blind man himself can find a home. Section six discussed plans for the extensive documentation of the various schemes of caring for the war cripples so that no useful bit of knowledge should remain local.

An extremely interesting feature of the conference was the exhibition of charts, statistics, and photographs, artificial limbs, inventions, games, and modifications of the tools in use in the ordinary trades by which they may be adapted to the cripple. Almost half of the French cripples, it was found, belonged to the agricultural class, and hence the French tools were largely of that kind. At the end of the conference all these exhibits were removed to the permanent war medical and surgical museum of Val-de-Grâce, where, no doubt, they will be exhibited in 2017 as marvels of crudity.

Many things were brought out by this conference, aside from the demonstration of *solidarité morale* among the Allies, which cannot but have a beneficent psychic effect. The various countries seem to be progressing in a fairly uniform manner along the same path, their progress varying only according to national conditions. The lot of the war cripple will undoubtedly be an easier one than it has been in the past. For one thing, the tremendous depletion of the working population of the nations will make such a scarcity of labor that these cripples will be welcome even if they cannot do as much as sound men. Then, too, so ingenious are the devices for remedying physical defect that in many cases the cripple can be rendered self-supporting, in other cases partly so.

The war cripple then will not be a pauper. He will not have to go through life accepting charity from the country he has helped, and suffering the consequent inevitable deterioration of his self-respect. The United States will undoubtedly follow the lead of our Allies, and, it is to be hoped, will find many ingenious methods of aiding the returned soldier to make up for the arm or leg he has left in France.

ETHER-OIL COLONIC NARCOSIS IN THE RUSSIAN ARMY.

THE Petrograd journal *Vraeh* for March 25 is devoted very largely to this subject, no less than five original articles having been contributed by as many army surgeons. The subject is

one which has excited the most active interest and a considerable Russian literature is already extant. An article by Protopopoff begins with an historical account of ether-oil narcosis. Nothing seems to have appeared on this subject in Russian until two years after the earliest accessible report of Gwathmey in 1913, the work of the Danes some twenty-five or thirty years ago having apparently been forgotten. From his own and the experience of his colleagues the author is able to draw up data as to advantages and contraindications. The latter are not numerous but include colitis, hemorrhoids, fistula of the rectum, and, in general, inflammatory phenomena of all kinds in the lower bowel. Among its advantages are, he thinks, the following: It is very convenient for operations on the head and neck; its technique is simple and adaptable; it is safer than other methods of narcosis (?); its operation is smooth and automatic, etc. A number of the advantages claimed are merely corollaries to others. Emphasis is laid on the fact that the action of the heart in debilitated subjects is augmented.

Markoff writes at great length on the same subject, giving his personal experience in considerable detail. He agrees with the opinion of an earlier writer—Gubareff—that it is a valuable acquisition to surgery. Yakovenko relates his experience with twenty-two cases and draws some brief conclusions. He commends its use in operations on the cranium, face, neck, and in part the chest. In weakened patients it is an advantage, and, in general, whenever chloroform or ordinary ether narcosis may be contraindicated. It may be administered by the ordinary practitioner. The author, however, recognizes certain disadvantages inseparable from the nature of the method.

Kramarenko deals especially with the untoward phenomena seen in connection with the method. In a certain number of cases the anesthesia has to be completed by the use of inhalation; the sensibility of patients shows variability; it is not possible to control the narcosis or to dose the ether accurately. Two cases are reported in detail in which the use of the method was attended with disastrous results, illustrating the danger of severe bronchorrhea despite the previous injection of morphine. The only fatality, however, which has been placed on record took place eight hours after completion of the operation. It was not a military case, the patient, a young man, having been the victim of a fibrosarcoma of the left half of the nose. Before intervention he received a morphine injection. The colonic mixture consisted of 150 c.c. of ether and 100 c.c. of oil of sesame. The operation was successfully performed. There was but slight hemorrhage, controlled readily with a tamponade. Pulse and respiration were good during the operation. At its completion the patient was placed in bed under the charge of the Sisters of Mercy. About five hours later there was a sudden fall of pulse and despite the application of all possible remedies the patient could not rally, death occurring, as stated above, eight hours after operation. At autopsy nothing was found to account for the death. The fact is of interest that with close control of patient, both during and after operation, collapse should appear without the slightest apparent cause or warning and fail to respond in the least to the usual treatment. This death occurred in the very class of cases in which the ether-oil narcosis is most commonly recommended.

Despite the fact that the ether-oil narcosis has been employed in hospitals in which there should have been thousands of wounded soldiers the case material shows that but few wounded were anesthetized in this manner. Such narcosis would not of course be selected for first interventions after injury at the front. Most of those operated on were soldiers with affections not due to their calling and which would naturally render them unfit for service, as tumors, aneurysms, etc.

MUSHROOM POISONING.

We find in the *Revue Médicale de la Suisse Romande* for May, 1917, two articles on this subject. The first, by Rock, gives twenty-four histories of 99 cases, the poisoning incidence being usually multiple—in one episode 14 having been attacked jointly. These cases all occurred in the neighborhood of Geneva, in the fall of 1916. Of the 99 cases, 3 ended fatally. The condition is as serious to the community as some of the infectious diseases. If the ratio is the same throughout Switzerland as it is in the Geneva region, the morbidity from this cause should be 1900 cases annually. In regard to the source of error, a trained mycologist is never poisoned except by inadvertence. In most other cases it is rank stupidity in people who erroneously believe themselves to be connoisseurs, and who have a sort of pseudological system for distinguishing between edible and poisonous mushrooms and for detoxicating the latter. A mycologist makes no mistake, because he has only to identify the edible and poisonous species; and while there are certain criteria in use which would exclude some edible fungi, this is merely acting on the safe side. Very many of the 99 cases of mushroom poisoning were found to have been due to the *Entoloma lividum*, which nature seems to have framed with the especial purpose of deceiving the inexpert. It is large, with beautiful white flesh, delicate, with appetizing, exquisite odor. An amateur who grew this species because of these qualities, and who had always believed them to be edible, was saved from disaster only when his excessive prudence led him to consult a mycologist, who, however, had all he could do to convince the grower of his error.

About one-half of the cases of mushroom poisoning can be traced to the *Amanita phalloïdes* and its congeners. Characteristic of poisoning by these species is the prolonged incubation period. They cause profound dehydration, so that the injection of

isotonic saline infusion is indicated. Hemolysis never occurs. *Amanita muscaria* produces a characteristic pseudo-drunkenness. In treatment there is no room for fads of specific procedure. Plenty of water and saline infusion with laudanum and heart stimulants are the remedies to use.

Gautier and Saloz publish an interesting case of poisoning by *Amanita phalloïdes* in which death occurred after the patient was apparently out of danger. A robust man of 45, familiar with edible fungi, ate some wild mushrooms of his own picking. They comprised several varieties, only one of which was unfamiliar to him, but this was guaranteed by a friend. He ate them at noon and at 10.30 P. M. was suddenly taken ill with atrocious cramps and presternal suffering followed by vomiting and profuse serious diarrhea. The following day he came to the medical clinic, reeling as if drunk, and with a syndrome of cholera, cramps in the calves being prominent. He did not improve after gastric lavage and caffeine injection. He presented cyanosis without dyspnea, and was profoundly collapsed. The liver was not enlarged, anuria was complete, pupils strongly contracted, mind clear. There was intense abdominal pain and tenderness, and the body was markedly dehydrated, but there was no hemolysis. Despite the desperate condition the patient rallied, and his general state alternated until the twelfth day of illness, when he seemed well enough to go home. However, on resuming work he found himself far from well, was weak, without appetite, and passing little urine. His gums bled, and he was markedly constipated. There appeared later a dry colic and nausea, with staggering, which caused him to take to his bed, where he became stuporous. Eight days after his discharge he was back at the clinic, where he died, just 30 days after his fatal meal. A few similar cases of such deaths after apparent recovery are upon record.

A Conception of Neurasthenia.

The term neurasthenia is employed to cover so wide a field that not a few physicians are even yet very sceptical regarding its existence as a morbid entity. Specialists have ascribed its causation to those affections in which they are chiefly interested. Some ophthalmologists affirm that neurasthenia is due in the majority of cases to eyestrain; the Arbuthnot-Lanes and those who trace all the ills of human flesh to deviations from the normal in the mechanism of the intestines preach the gospel that it is owing to intestinal stasis; many nose and throat specialists look upon a deviated septum, bringing about deficient oxygenation of the blood, as responsible for the train of neurasthenic symptoms. Leonard Williams in the *Practitioner* for July, 1917, joins the chorus and gives his views with regard to its causation. As befits one, who is peculiarly sensitive to the wiles of the endocrine glands, he declares his belief that when these glands become inactive, the subjective symptoms of neurasthenia become vocative and even vociferous. Moreover, he holds that neurasthenia being a circulatory matter, should not provide cases for the neurologist but rather for the cardiologist or surgeon. As for treatment, the remedy lies in the purification and the correct composition of the blood supply. The purification refers to drainage and the good composition to the tribute of the endocrine glands. In short, Williams insists upon the practical identity of the symptomology of true neurasthenia with that of suprarenal insufficiency.

Red Tape versus Ordinary Sense.

A very large number of the registrants between the ages of 21 and 31 who have been drafted are manifestly exempt; many others claim and probably will be granted exemption. Nevertheless every drafted man must first be examined medically. The medical examiners are working without pay, losing much of their practice temporarily, animated solely by motives of patriotism. Yet they must in many instances waste hours and days of their precious time examining men who will probably if not surely be exempted later. (It takes thirty minutes or more to examine each man properly.) Another instance: A young man, within the registration age, enlisted in the navy, passed a satisfactory physical and mental examination, and was made a quartermaster. His number was called in the draft, and now he is notified by the provost marshal general's office to present himself for examination, "as the rules require examination even when the registrants are in the service." The *Official Bulletin* of August 1 contains a notice from Provost Marshal General Crowder that medical students who are drafted cannot be exempted, and this despite the medical famine in England and France due to just such folly. Comment is superfluous.

News of the Week.

Plea for More Accurate Death Certificates.—The Bureau of Census is planning to prepare and publish a monograph on the mortality from tuberculosis covering the calendar year 1918. To make this work of greater value, an endeavor is being made to obtain the cooperation of all physicians to the extent of carefully recording or supervising the statements of occupations upon the death certificates during that year. Circular letters have been sent to all the physicians in the United States, calling attention to the importance of such statistics, and urging them to take pains to see that the occupation items upon each death certificate are properly supplied.

Increase Resources of County Tuberculosis Hospitals.—With a view of mobilizing all the resources which will assist the counties of New York State in carrying out the provisions of the recently enacted law requiring the construction of tuberculosis hospitals in counties of 35,000 population or more, the State Commissioner of Health, Dr. Hermann M. Biggs, has appointed two committees which are to take entire charge of the tuberculosis situation in this State. The first committee will have general supervision of the sites, plans, construction, and equipment of tuberculosis hospitals, and will carry on the anti-tuberculosis campaign in

the State. On this committee are Dr. John A. Smith, Dr. O. R. Eichel, Dr. E. S. McSweeney, with Dr. Matthias Nicholl, Deputy Health Commissioner, as a member of the committee ex-officio, and also a construction and an engineering expert. The second committee is an advisory committee, consisting of Dr. Albert H. Garvin, Dr. John S. Billings, Dr. Charles Stover, Dr. Horace J. Howk, and Dr. Lawrason Brown.

Determination of Food Values.—The Carnegie Institute of Boston is to conduct a series of experiments this fall to demonstrate whether men and women cannot maintain their powers on a smaller ration than has hitherto been accepted as the minimum. The Battle Creek Sanitarium has just finished a metabolism experiment lasting forty-five days, with ten subjects. The object was to determine the effect of different diets on the chemical composition of the blood. The results have not yet been tabulated.

State Food Bill Framed.—A composite bill, including the best features of the National and the Whitman food-control measures, has been introduced into the New York Legislature, which is in special session. Governor Whitman does not favor giving the proposed State food commission of three members power to commandeer food products except those hold in cold storage by food speculators.

Bequests.—St. Mary's Free Hospital, Sea Breeze Hospital, Association for Improving the Condition of the Poor, and Charity Organization, New York City; Morristown Memorial Hospital, New Jersey, and All Souls' Hospital, receive $10,000 each by the will of Annie A. Peckham.

Feeding Children from Two to Seven Years Old.—A survey of leaflets giving advice on diets and food economies has disclosed the fact that little attention was being paid dietaries for children between the ages of two and seven years. At the request of the Department of Health, the Advisory Council of the Health Department, consisting of Drs. L. Emmett Holt, Graham Lusk, Linnaeus LaFetra, and Godfrey R. Pisek, have issued a statement on this subject, which is published in the Weekly Bulletin of the Department of Health for July 28. The caloric value of various food stuffs is given, the cost per calory, methods of cooking, and sample diets for children from two to four and from five to seven years of age.

Fatalties Caused By Heat.—The heat wave which culminated on August 2 resulted in the longest list of deaths and prostrations due to heat ever tabulated in national or local torrid-weather history. It is stated that in the metropolitan district 135 persons died directly as the result of the heat and that there were over 400 prostrations, ambulances and hospitals being kept busy. Washington estimated that more than 300 persons lost their lives and more than 800 were prostrated in the territory swept by the hot wave. Brooklyn broke her record for ambulance calls, which was 178 on July 4, 1915, by creating a new one of 225 for August 1.

Inspection of Soda Fountains.—All soda fountains in the city of Syracuse are being inspected this summer by city health officials. A score card has been prepared, and fountains falling below a specified average are being closed.

Prof. Theodore Kocher died at Berne, Switzerland, on August 1. Professor Kocher was the recipient of the Nobel prize for surgery in 1909, and was one of the greatest surgeons of his time. He was born at Berne in 1841, and studied medicine in Berne, Berlin, London, and Paris. He was professor of surgery at the University of Berne.

Restrictions on Rockefeller Foundation Removed.—The stipulation that $2,000,000 of the annual income of the Rockefeller Foundation is to be expended at the direction of John D. Rockefeller has been waived. The trustees of the Foundation have been given free rein to use the entire yearly revenue and, if necessary, part of the principal as they deem wise to meet the exigencies of war.

Examination for Office of Chief Medical Examiner.—The Municipal Civil Service Commission announces an examination for the position of Chief Medical Examiner of the City of New York. Physicians more than 30 years of age, who have had ten years' experience in a pathological laboratory, have until August 14 to file applications. The examination is to fill the place of the coroners who will by act of Legislature go out of office January 1. The position carries a salary of $7,500 a year.

Civil Service Positions.—The Civil Service Commission of the State of New York announces the following examinations to be held September 8, and for which application must be made before August 29: Diagnostician and epidemiologist in State Department of Health, salary $3,500, open to men and women, and limited to physicians; medical expert on tuberculosis, salary $3,200, open to men and women, and limited to physicians; assistant to the deputy commissioner, salary $3,500, for men only; bacteriologist, salary $2,000, open to men and women, minimum age 25 years, a degree in medicine or an equivalent education in a college maintaining a standard satisfactory to the commission, or training and experience in chemistry, is desirable but not essential. Persons desiring to take any of these examinations should write to the State Civil Service Commission, Albany, N. Y., for special circular of information.

Smallpox in New York State in 1916.—The July Bulletin of the Department of Health of New York State shows that thus far in 1917 smallpox has appeared in 11 counties of the State, with a total of 58 cases with two deaths. There were during 1916 23 cases. A study of the source of the disease shows that though the cases were widely scattered they could all be traced to a few definite sources, the epidemic in Chautauqua County being clearly traced to a man who contracted the disease in Wisconsin, and the outbreak in Beacon County to Waterbury, Conn. The report emphasizes the fact that as usual the victims were unvaccinated persons.

The Care of Expectant Mothers.—The New York Milk Committee has just published a report of an experiment in the care of expectant mothers covering a period of four years. During the four year period 3,145 expectant mothers were enrolled and given care and supervision averaging three and one-half months before and one month after confinement. Each mother was visited in her home every 10 days by a trained nurse and by a physician

when necessary. When the babies were one month old they were registered at the Department of Health Milk Stations. There were 3,192 babies born to these 3,145 mothers. Of these 115 were still births and 86 others died during the first month after birth. The still birth rate per thousand of these cases was 36 against 46 for the Borough of Manhattan, or a reduction of 22 per cent. The rate per thousand of deaths under one month was 28 against 39 for the borough, or a reduction of 28 per cent. Of this entire group of mothers only five died, giving a rate of 1.5 per thousand against a rate of 4.9 in the city at large, or a reduction in the maternal mortality rate of 69 per cent.

The Starvation Treatment of Diabetes.—In the review of this book appearing in the issue of July 7, the price was erroneously stated to be one dollar; it should have been given as $1.25.

The American Climatological and Clinical Association, at its thirty-fourth annual meeting held in Lakewood, N. J., on May 29, 30, and 31, elected the following officers: *President,* Dr. J. H. Elliott of Toronto, Canada; *Vice-Presidents,* Dr. W. G. Schauffler of Lakewood, N. J., and Dr. H. M. Bracken of St. Paul, Minn.; *Secretary,* Dr. Guy Hinsdale, Hot Springs, Va.; *Recorder,* Dr. W. Duffield Robinson, Philadelphia.

The Eighth District Medical Association of South Carolina, which met in Saluda, S. C., July 11, elected the following officers: *President,* Dr. L. J. Smith of Ridge Spring; *Vice-President,* Dr. J. B. Edwards of Monetta; *Secretary,* Dr. R. A. Marsh of Edgefield.

Licensed to Practise Medicine.—At the recent examination of the State Board twenty-seven men were licensed to practise medicine and surgery in the State of South Carolina and one woman was licensed to practice osteopathy.

Dysentery in Germany.—It is reported from Holland that a serious epidemic of dysentery is threatened in Berlin, Hamburg, and Bremen, many cases of the disease having occurred in these and some other German cities.

Drug Selling Gang Rounded Up.—Five young men who have been selling habit-forming drugs to men in naval uniform in the vicinity of the Brooklyn Navy Yard were hunted down by an agent of the Department of Internal Revenue and taken into custody by the police. Over one thousand bottles of heroin and cocaine were seized. It is said that they were selling on an average of forty bottles of narcotics daily in the neighborhood of the Navy Yard.

Need Funds for Sick Babies.—The Floating Hospital of St. John's Guild, New York, is making an urgent appeal for money with which to carry on its work. The Floating Hospital carries 1,000 sick babies and their mothers daily and the Seaside Hospital wards are crowded with sick babies.

Obituary Notes.—Dr. THOMAS J. THORNBURY, retired, died at his home in Forest Hills, L. I., July 29, at the age of 78 years. He practised medicine in New York City for forty years and in Brooklyn for five years.

Dr. HARVEY H. CONVERSE of Eastford, Conn., a graduate of the American Eclectic Medical College, Cincinnati, in 1878, died suddenly, July 9. Dr. Converse was a Civil War veteran.

Dr. HOWARD W. BASSETT, a graduate of the Medical College of Virginia, Richmond, in 1906, died at his home in Richmond after a long illness, on July 15, aged 56 years.

Dr. MARY H. BAYNUM, for many years a practitioner of Dexter, Me., died after a series of paralytic shocks, on July 15. She was a graduate of the Boston University School of Medicine, in 1885.

Dr. JAMES ALLEN NICOLS, a graduate of the Long Island Medical College and Hospital, died at his home in New York City, July 28, at the age of 58 years.

Dr. WELLINGTON JEFFERS, a graduate of the Victoria University Medical Department, in 1867, and a practitioner of Linsay, Ontario, died after a brief illness, on July 17, at the age of 71 years.

Dr. JAMES COWPER HANNAN, a graduate of the New York University Medical College, in 1873, for many years a practitioner in the Bronx, New York City, died August 2.

Dr. ADOLPH E. LOBERG of Minneapolis died from pneumonia on July 18, aged 41 years. He was a graduate of the University of Minnesota, Minneapolis, in 1901.

Dr. LINUS E. RUSSELL died of apoplexy at his home in Springfield, Ohio, on August 2, aged 66 years. He was a graduate of the Eclectic Medical College of Cincinnati in 1872, and for many years professor of obstetrics and gynecology in that institution.

Dr. WILLIAM RICHARDSON, a graduate of Dartmouth Medical College in 1883, and for many years a practitioner of medicine in Londonderry, N. H., died on July 25, aged 57 years.

Dr. JOSEPH W. MACDONALD, a graduate of University of Bishop College, Faculty of Medicine, Montreal, in 1878, died at his home in Manchester, N. H., July 25, at the age of 66 years.

Dr. ARTHUR WELLINGTON SMITH died at his home in Nashua, N. H., on July 21, aged 64 years. He was a graduate of the Dartmouth Medical School in 1876, and stood high in Masonic circles.

Dr. AUGUSTUS A. GREENBERG died in the Jewish Hospital, Brooklyn, from blood poisoning, on August 6, aged 38 years. He was a graduate of the Long Island College Hospital in 1909, and on the visiting staff of Gouverneur, Mt. Sinai, and Beth Israel Hospitals. He was to have reported to Fort Benjamin Harrison on August 10, to take his assignment as first lieutenant in the Medical Reserve Corps.

Dr. LESLIE T. PAGE, a graduate of the University of Vermont Medical School in 1891, died at his home in Lewiston, Me., on July 21, aged 51 years. Dr. Page spent the active portion of his professional life in Wilmington, Vt., going to Lewiston for his health last September.

Dr. ADOLPHE A. AUDREAN died at his home in Chicopee, Mass., on July 21, aged 77 years. He was born in France, and for some years lived in Montreal, Canada, where he held several prominent political posts. He later came to Chicopee, where he practised medicine for 39 years.

Dr. JOHN HAMILTON POTTER HODGSON of New York City died suddenly at Toronto, Canada, on August 4, aged 48 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1889, an alumnus of the City Hospital, and a member of the Academy of Medicine.

(From Our Regular Correspondent.)

MENTAL HYGIENE AND SHELL-SHOCK

LONDON, July 14, 1917.

DR. F. W. MOTT devoted the Chadwick Lecture to the subject of "Mental Hygiene and Shell Shock," treating it in reference to the war, during and subsequently to that event. He applied the term to a group of varying signs and symptoms indicating loss of functions and to disorder of the functions of the central nervous system produced by exposure, either sudden or prolonged, to forces generated by high explosives. It may also be caused by cerebral or spinal concussion, though no injury be visible. Sandbags hurled from a distance and striking an individual on the head or spine have often furnished examples of this. Soldiers have sometimes suffered by the roof or wall of their dugout being blown in; others have themselves been driven by the force of an explosion against the wall or roof. The force generated by a 17-in. shell has been calculated as equal to 10,000 kilos per square meter, or 10 tons to a square yard, supporting in this the conclusion that death may occur as the result of aerial concussion produced by high explosives without any visible injury. Perhaps such death may be due to sudden arrest of the vital centers. The cerebrospinal fluid restrains oscillation of both anterior and posterior cerebral roots as well as of the ligamentum dentatum. Consequently that fluid acts as a water jacket to the spinal cord and a water cushion to the base of the brain. This fluid not only surrounds the central nervous system, but it fills up the hollow spaces, the ventricles and the central canal, as well as all the interstices of the nervous tissues; consequently a strong enough shock to the fluid would affect the delicate colloidal structures of the living tissues of the brain and cord. This would occasion disordered function or even loss of function. The higher centers would most likely suffer first, and it is often difficult to determine the point. The lecturer called attention to another factor sometimes complicating shell-shock. A soldier lying unconscious may be exposed to noxious gases generated by shells or mines. It is said that malingering as shell-shock is not uncommon and detection of the fraud by no means easy, for a functional neurosis due to a fixed idea may be mistaken for that condition.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

DERMATOLOGY OF THE WAR

PARIS, July 20, 1917.

THE diseases of the campaigning soldier differ considerably in nature and frequency from those encountered in times of peace. In the dermatological clinics of the Paris hospitals before the war, one would encounter as the most frequent forms of dermatosis, eczema, scabies, psoriasis, and tuberculous troubles under lupic or varicose forms. Today eczema, tuberculides, and scabies are rare, being replaced, in order of frequency, by phthiriasis, eczema, and trichophytinous diseases, oftentimes marked by varied peculiarities.

During the winter months there frequently appear several varieties of artificial forms of dermatitis; there are unusual forms of impetigo of the face, sycosis of non-parasitic origin, and particularly the subnasal form is frequent.

Tuberculides and tuberculosis of the skin are rare. This is not astonishing when one is acquainted with the rigorous care with which tuberculous subjects were eliminated by the medical examiners as the soldiers presented themselves for active service. The army life and exercise in the open air; the nourishment, good in quality and quantity, have constituted great obstacles to the development of the attenuated forms of tuberculosis of the skin.

Phthiriasis has been the disease in common evidence and chiefly in the acute form, which is rarely seen in ordinary times. In many cases the invasion of the parasites is so sudden and so abundant that nearly the whole of the body will be covered by small edematous papules of the size of a pinhead, resembling urticaria. The papules of excoriated prurigo, with their small black-brown crusts, habitually seen in phthiriasis are the exception; equally rare is the melanodermy common to chronic phthiriasis.

The sudden invasion and early care of these cases confined them to the acute manifestations, but with the more prolonged and exacting duties of this summer's campaign the papules of excoriated prurigo and melanodermy are beginning to appear. One of the marked peculiarities attending this disease among the soldiers is that they almost constantly present an ecthyma of the inferior members; these resemble artificial wounds, and when seen for the first time have been mistaken for voluntary mutilation, but were found to be the result of scratching by infected nails. The soldier standing upright reaches down and scratches himself.

Several articles have been published in the French medical press calling attention to the recrudescence of psoriasis observed among the soldiers resulting from nervous shock, violent emotion, or traumatism. Following the destruction of the "Jena," one of the soldiers had hospital treatment for a brusque attack of psoriasis resulting from violent emotion produced by the explosion.

A young soldier of twenty-two suffered an attack which appeared generally distributed over the whole body immediately following his first charge upon the trenches of the enemy. Another soldier, twenty-eight years old, had an eruption of this disease generally distributed over the trunk and arms following the explosion of a "marmite," which knocked him down but produced no wound. A young woman of twenty-five presented this eruption immediately following the bombardment of Arras, where she was living. A number of cases of this disease have been reported following wounds.

At the beginning of the war there were gathered five or six thousand head of cattle at Verdun to furnish meat to that entrenched camp. The soldiers in charge of the cattle were attacked with trichophytis, which appeared generally all over the body. It spread to the artillery and all the branches of the service where the men came into contact with animals.

There has been a remarkable absence of itch

among the soldiers. It would appear that men do not catch this disease from each other under the ordinary conditions of campaigning; that is, clothed and sleeping side by side in straw or on the ground.

2. Biologic Analysis in the Study of True Epilepsy.—F. L. Dunham considers that whether true epilepsy is to be regarded as a simple neurosis, as a manifestation of organic disease with evidence of cerebral toxemia, or as an "unconscious striving, with its insistent urge in the fits, to return to the maternal intrauterine life," analyses following biologic lines only are justified as a means toward the recognition of potential subjects. Until the facts of such an analysis are secured no amount of pathological detail can render practical service in the disposition of individual cases. Twenty cases were analyzed and the data for analysis were secured from the following examinations: (1) An anthropological examination. (2) An intelligence test (point-scale) checked by a second (Binet-Simon) test. (3) A complete physical examination, including an examination of the urine. (4) A Wassermann reaction. (5) An examination of the social history of the family, so far as possible through personal solicitation, otherwise by questionnaire. The subjects were also studied in their customary environment, now playing or working in groups, at other times alone with an attendant. An attempt was made to place each child at his ease by engaging him in some task, thus minimizing the changed emotional reaction incident to any examination, with its resulting inaccuracies. The various factors reported show conclusively that the prenatal environment of each of these individuals was modified sufficiently to induce, in any organism, profound structural changes. The objection may be raised, however, that this offers no explanation of the specific defect. Why epilepsy instead of idiocy or a monster? To this the only reply is that the various objective results of the process seem to differ in degree only. All cerebral disturbances presuppose some specific defect of organization. Idiocy and epilepsy are frequently synonymous, and the epileptic has many physical stigmata which are the hall marks of the monster. It is of interest to note in this connection that recent investigation points to the conclusion that the primary causes underlying the origin of monsters in man and other mammals are autogenous chemical modifications of the parental blood. Working with butyric acid and acetone, Werber concludes that all morphological deformities of sensory organs may be induced through the blastolytic action of the modified environment. Dunham further states that the epileptic's failure to make a good social adjustment follows as a logical consequence of his biologic defects. Conduct results from the activity of emotions and impulses springing as natural growths from the primary instincts. As a result of the organization of these emotions, the sentiments develop—systems of the utmost importance in the formation of character. Consequently the child having epilepsy, whose basic instincts and mechanisms are at fault, is deprived of these organized elements of the affective processes, into whose composition enter the principal emotional dispositions of the instinctive life. The natural result of this defect is an unstable and incomplete social adjustment. He states that in the foregoing analysis an attempt is made to emphasize the importance of the more intensive, biologic examination of children—in this instance, those afflicted with true epilepsy. An explanation of epileptic phenomena is sought in the reactions of noxious stimuli upon the germ cell, whose environmental maladjustment appears to induce abnormal, morphological differentiations in the embryo with the power of hereditary transmission of tendencies toward defect, to succeeding generations. An analysis is made of various phenomena in the social, somatic and psychic behavior of twenty subjects suffering from true epilepsy. Attention is called to these as evidence of instinctive instability. The recognized hypothesis that structural abnormalities are concerned in the production of epileptic seizures is accepted and the unconditional reflex is suggested as an element in their mode of functioning.

2. Race Betterment Based upon Principles of Physical and Mental Prophylaxis.—Alfred Gordon in his address at the commencement exercises of the College of Physicians and Surgeons, Boston, June 12, 1917, concluded his address by urging that physicians study the problem of race betterment, that they keep pace with new facts, and that they develop an enlightened interest in ideals of eugenics in every one with whom they came in contact. The task is a difficult one but if at least some people can be convinced that the social evils can be prevented, that the defective intellect, the criminal tendencies, and the degeneracy of the child all originate from a pathological parentage, the physician's contribution to mankind will be of the highest order. The rôle of the physician does not lie exclusively in removing suffering. His mission must be a higher one. Who, if not the physician, can serve as the best guide to an honest man who undertakes to lay the foundation of a family? The physician alone can avert danger by emphasizing to the candidates for marriage the laws of heredity and the consequences of morbid heredity; he alone can make it clear to any man or woman that to read daily on the face of their child the stamp and the reproach of a morbid taint which they tried to conceal is more torturing than the stain of blood of Macbeth. To combat social misery and all its consequences is to combat physical and moral deterioration. Preventing them means to prepare generations better equipped to resist depressive influences in life and therefore more apt to receive an intellectual and moral foundation which will transform them. *Fortes fortibus generantur* is the logical conclusion drawn from the application of biological knowledge to social evolution.

6. The Clinical Significance of Gastrointestinal Toxemias.—E. E. Smith sums up his subject by stating that in his present presentation it has been his purpose at a time when everyone is particularly enthusiastic about another form of toxemia, namely, protein sensitization, to call attention to the condition of intestinal autointoxication, which is apt to be forgotten. The technical difficulty of obtaining adequate data in these cases, the careful study of individual cases necessary to exclude other conditions, and the extravagant and erroneous claims of the Metchnikoff school which overpopularized this subject at the expense of accurate information, should not cause us to overlook this condition as a real factor in many of our cases. It is suggested by the clinical symptoms and is to be further recognized by the intestinal flora and by the products absorbed and eliminated in the urine.

4. The Production of an Antipoliomyelitis Serum in Horses by Inoculation of the Pleomorphic Streptococcus from Poliomyelitis.—Edward C. Rosenow states that a restudy of the bacteriology of poliomyelitis during the past epidemic has emphasized anew the possible rôle which bacteria of ordinary size may play in the etiology of this disease. A pleomorphic streptococcus or micrococcus having elective affinity for the central nervous system in animals has been isolated quite constantly from the atrium of infection and the central nervous system, the brain and cord and the spinal fluid in human poliomyelitis, and from the central nervous system of monkeys paralyzed with virus. Neustaedter and Banzhaf, among others, appear to have developed a neutralizing serum in a horse by injecting large doses of filtrates of active virus. Rosenow records the essential facts in the immunization of horses with cultures of the pleomorphic streptococcus, the results of experiments in neutralizing and protecting against virus with the immune serums thus obtained, and the findings of agglutination and complement-deviation studies, as carried out under his supervision and direction. He says that through this work it has been shown that: (1) The serum of horses immunized with aerobic cultures of the pleomorphic streptococcus from both poliomyelitis in man and experimental poliomyelitis in the monkey developed specific antibodies, agglutinins and complement-deviating properties, the agglutinins appearing to be present in large amount because the serums cross-agglutinate these strains specially in very high dilutions. (2) The serum of patients and monkeys which have recovered from attacks of poliomyelitis cross-agglutinates specifically many, but not all, of these strains in the lower dilutions. (3) What is of greatest significance, the serum of the horse immunized with recently isolated strains from experimental poliomyelitis in the monkey appears to have developed neutralizing, protective and curative power against the virus of poliomyelitis.

2. On Skin-grafting: A Plea for its More Extensive Application.—S. R. Douglas, L. Colebrook, and A. Fleming state that it ought to be possible, in theory at least, to cut short the tedious stage of the healing process of wounds which require assistance in the healing by the application of skin grafts, yet the operation seems to be commonly regarded as a last resort and is comparatively seldom practised; for, since the commencement of the war, only two short contributions to the subject have appeared in the *British Medical Journal*, and in *The Lancet* a single (although very important) letter. In 1869 Reverdin introduced the method of implanting tiny portions of skin upon granulating surfaces to serve as centers of growth. Steele in 1870 improved upon this by cutting the grafts rather larger and thicker in order to obtain stronger and more elastic scars. His grafts varied in size from the diameter of a pea to that of a three-penny piece or even larger. Both of these methods appear to have been widely practised and with considerable success. They were given up, however, in course of time because of the more rapid and striking results sometimes achieved with the method introduced later by Thiersch, which aimed at covering the entire wound surface with grafts at a single operation. The Thiersch method, in turn, was found to have serious disadvantages; in particular, the adhering of the grafts was uncertain, and the scars resulting from it were often unsatisfactory. Recognition of these drawbacks and forgetfulness of the older methods have resulted in the operation of skin-grafting being now seldom practised, in spite of the great opportunity at present afforded to make use of it. The authors have revived the use of Steele's grafts and introduced certain new features into both the grafting operation and the after-treatment, which aim at making the transplantation of skin a simple, reliable procedure. With respect to the grafting operation the chief new, or at least unusual, features are: (1) The use of local anesthesia induced by nerve blocking; (2) the suture of each of the raw surfaces left after removal of the grafts. With regard to aftertreatment the authors have been influenced by the recognition of the important part played by the tryptic action of pus, which recent work has explained and emphasized. There is little doubt that neglect of this factor has been one of the commonest causes of failure of skin-grafting operations; in consequence the aftertreatment advocated has aimed especially at preventing the accumulation of pus while avoiding at the same time any movement of the grafts. The means employed to achieve this were: (1) The employment of a new and suitable material to hold the grafts in position and allow the escape of any discharge from the wound; at the same time it permits the surface to be efficiently cleansed at frequent intervals. (2) The daily change of the outer dressings, which are kept constantly moist with some bland fluid. The advantages claimed for the methods advocated are that: (1) Successful results can be obtained much more constantly. (2) The use of a general anesthetic is dispensed with. (3) The raw surfaces left after the removal of the grafts, being closed with sutures, heal rapidly and certainly. (4) The resulting scars are stronger, more elastic, and less prone to ulceration than those resulting either from Thiersch's grafts or from the natural healing of wounds. In addition, it is probable that by early grafting it will be possible to prevent many of the deformities due to the contraction of scar tissue. The results obtained in 29 transplantations of Steele's grafts are given as follows, 22 of which were autodermic and 7 isodermic; 80 to 100 per cent. of the grafts adhered in 18 out of these 29 cases; 48 to 80 per cent. adhered in 7 of the 29 cases; while 5 to 15 per cent. adhered in 3 out of the 29 cases. Section grafting was employed in four cases, two of which were perfect successes and the remaining two partial successes.

8. The Croonian Lectures on Adaptation and Disease (concluded). J. G. Adami.

2. The Department of Oral Surgery of the Harvard Surgical Unit.—V. H. Kasanjian gives a report of some of the advances that have been made by the Department of Oral Surgery of the Harvard Surgical Unit as a result of their work at the war. They are as follows: (1) A realization of the importance of immobilization or reduction of maxillary fractures at the first possible moment along the lines of normal occlusion of the teeth. (2) Early reduction of sepsis by small and timely operations with a local anesthetic. (3) A better understanding of the dangers attending the use of general anesthetics for operations on patients suffering from face and jaw injuries. (4) The control of severe complications, especially of secondary hemorrhage. (5) The modification and simplification of many types of oral

splints. (6) Temporary and permanent oral restorations. (7) The use of local anesthesia for extensive plastic operations about the face, mouth, and neck. This summary of the work has not included an appreciable number of cases which have been treated from necessity in other hospitals, nor a large number of patients who have received attention for dental and oral complications.

3. **A Note on Oral Surgery.**—A. C. Valadier and H. Lawson consider that the advances in the surgery of the jaw and face have been gradual, but as the result of experience a few points have crystallized out with distinctness. These points are: Speaking generally of facial wounds, it is advisable to delay considerably before doing final and finishing operations, but not at all before the primary sewing up. The most common serious sequelæ of war injuries to the jaw have been recurrent and secondary hemorrhages, inhalation pneumonia and gangrene of the lung, and mediastinitis. Down to January, 1917, they had among 1010 cases twenty-seven deaths, seven of these from pneumonia. There were three tracheotomies (including one emergency laryngotomy) and eleven hemorrhages necessitating ligature of the external, and three of the common carotid. These three latter are all living, and apparently not suffering any discomforts as a consequence of this operation.

4. **Nnte on Flavine, Sodium Desoxycholate, and Quinine as a Mouth Wash.**—F. M. Wells reports on his laboratory examination of the effects of the above combination of antiseptics on the mucous membrane of the mouth. The examination was carried out on one mouth, controls were used, and plates were incubated for twenty-four hours, and counts were made. The most favorable results were obtained from a combination of desoxycholate 2 per cent., quinine 0.25 per cent., and flavine 1 in 2000. The quinine desoxycholate solution has a considerable bactericidal effect on bile-soluble cocci, and on other cocci as well, and in the strength used it appeared to have no irritant effect on the mucous membrane. Wells further states that judging from the chemical action of the desoxycholate and quinine tablet, it should be an excellent treatment for infected throats, as in the strength used in these tablets all the pneumococci strains are easily destroyed without causing any irritation on the mucous membrane. This pathogenic group alone is giving more trouble than any other strains to be found in the mouth and throat. Again, amebæ are very easily cleared out of the mouth with sodium desoxycholate and quinine in the strength used in these tablets, as he has found in cases of pyorrhea caused by amebæ. In the solutions containing the above-mentioned antiseptics the bacterial count, even after four hours, was in most cases considerably less than the control before treatment, whereas with the more irritating antiseptic solutions the count rises rapidly after the initial fall until it reaches a figure in excess of the normal. He considers this second rise to be a useful indication of an irritant effect on the mucous membrane. Tablets made of these antiseptics given above should have a stronger antiseptic power when dissolved slowly in the mouth than a mouth wash, as the tablet in dissolving would keep up a continuous action on the mucous membrane of the throat.

La Presse Médicale.

June 21, 1917.

Abortive Treatment of Typhoid Fever.—Mauté of Morocco writes on this subject, and first states that at present we have vaccines to prevent the disease, but as yet no real abortive remedy. He believes, however, that we are to have one in the intravenous injection of certain vaccines. By subcutaneous injections alone the finds are conflicting, while of seven men who have used the intravenous route all are agreed as to the benefits obtained—in fact, the conclusions are absolutely in harmony. The only American mentioned in this connection is Frederic Gay. However, to offset the striking abortion of the disease in certain cases is the violent general reaction which is in contrast with the slow course of the disease proper, and may end in collapse and death. In other words, the collateral results kill the idea of the treatment. Is this reaction controllable? Much or all depends on the dose and how can one so dose a vaccine as to make it safe? There is hardly any margin between a therapeutic and a toxic dose. If the amount injected is too small we get neither action nor reaction. There is clearly a marked personal equation. And how are we to be sure that this curative action is truly specific? A specific action need not be instantaneous—in fact, we know that more or less delay may be inevitable in known specific medication. The sudden, violent reaction is rather anaphylactoid. The author has therefore sought to use some relatively harmless animal protein, and selected a nontoxic saprophyte which he describes accurately but does not identify. He made an emulsion, which, tested in animals by hypodermic and intravenous routes, and parenterally was found to be free from toxic effects. With such an emulsion he treated 22 cases of typhoid by the intravenous method (100 to 500 millions). One patient only was lost, and he died of purulent peritonitis, following perforative cholecystitis. The injections were made in the morning, and in 19 cases there was defervescence to normal or subnormal, irrespective of the stage of the disease. After this act of defervescence the temperature in many cases went up slowly, and several days elapsed before it reached the normal high point, at which juncture a second injection produced a permanent defervescence. According to the accompanying curves, it is seen that in one case an injection (the second) caused permanent defervescence on th 14th day. In a second case an injection on the 10th day, with temperature at 40.5° C., was followed by a gradual defervescence which was complete on the 15th day. In a third case an injection on the 8th day caused complete defervescence. The temperature slowly ascended, and from the 13th to the 22d day of the disease never went over 39° C. A second injection was followed by permanent defervescence. In a fourth case an injection on the 15th day was followed by sudden permanent defervescence. From these few cases it appears that an injection about the 15th day gives the best or most ideal result. With the temperature fall there was invariably a general improvement. The rationale of the efficacy of foreign protein in typhoid is obscure.

La Presse Médicale.

June 28, 1917.

Causes of Chronic Appendicitis.—Faure states that this affection is extremely frequent. He uses the term to embrace a host of conditions, many of which are not inflammatory, although in part of inflammatory origin. Purely noninflammatory are calculous appendixes, some of which show mechanical ulcerations and simple constricted appendixes. All of these kinds of pseudo-appendicitis cause a syndrome like that of the actual disease, and may require operative treatment. Naturally they are much less deadly than the true disease. In the wide sense of the term the "chronic appendix" is of such incidence as to be well nigh universal. This is apparent to every laparotomist, and is perhaps the chief reason for perfunctory or routine extirpation of the organ. It is exceptional for the gynecologist to find a normal appendix in his female patients. Men no doubt suffer equally, although less obviously. Children suffer much less than adults. The appendix is a lymphatic, spongy structure, which can be infected by the blood or lymph route, as well as by the intestine. It is fully as vulnerable as the tonsil. Who has not had one or more attacks of tonsilitis? Yet the tonsil is much more favorably situated than the appendix to escape the consequences of infection. There is no chance for constriction, no nearby peritoneum. Like the tonsil, the appendix participates in many general infections. The author illustrates the following: congestion of appendix, punctiform hemorrhages, insular folliculitis, polypi, ulcerations—all of the lumen; forms of construction by mesoappendix, calculous appendixes, fibrous, or sclerous appendixes of various forms, cystic appendix. But despite the almost universal occurrence of the chronic appendix many escape trouble. In many others the only annoyance is digestive disturbance or pain. The latter, when present, may be due to a subacute exacerbation. Curiously, in the most painful

case the reason for pain is not obvious. Many cases are clearly benign, yet there is no means of discriminating. But appendectomy in benign conditions is a very safe intervention.

Rabies in Man.—Jourdran and Marchand first mention the great difficulty in diagnosis. The history of a bite and fatal termination are the chief evidences in clearing up a case. The authors have recently studied six cases, as follows: (1) Soldier, 32, bitten on wrist 40 days before, Jan. 1, 1917. No antirabic treatment. Locally lymphangitis and lymphademitis which did not persist long. Cerebral excitement first general symptom, followed by fever, vomiting, and dysphagia. When first interned he was exhilarated and anxious by turns. Intelligence was good, speech brief and rapid. Vomiting continuous, no headache, no Kernig. Muscles weak, hypotomi, some agitation. Dysphagia not accompanied by hydrophobia. Reflexes largely abolished. Pupils unequal, reactions sluggish. No hyperesthesia. Blowing on the face, and bright objects to the eye failed to produce spasms, or defense motions. Four days after admission death in syncope. Before this symptom he had called urgently for water. The dog was proved rabid. The second patient had taken antirabic treatment after his bites; nevertheless, in 27 days, he developed rabies. The affection began with fever and insomnia, followed by dysphagia and nuchal pains, sweating, and anxiety. Sudden blowing in the face caused spasm of the larynx, pharynx, diaphragm, and neck muscles. On the third day he began to vomit. With intellect clear, and knowing his end near, he dictated his will, but fell in syncope before he could sign it. The other cases occurred in native boys (Malguches), but apparently agreed in the main with the preceding. Three had received antirabic treatment. Phases of euphoria alternated with periods of anxiety. All but the first named of the six cases appear to have occurred in Madagascar, where for some reason the Pasteur treatment failed.

Correspondenz-Blatt für Schweizer Aerzte.

Dermographism as a Diagnostic Resource.—Schwartz considers this subject exhaustively. Known in the Middle Ages as a witch's mark, urticaria factitia was first mentioned in a medical publication by Rayer in 1840. In 1879 Dujardin-Beaumetz showed an "autographic woman" to the members of the Paris Medical Society. There is no dearth of literature on the subject. In a recently published graduation thesis (1911) Polonsky digested no less than 50 articles, while Barthélemy contributed a monograph of 300 pages in 1893 (*Étude sur le dermographisme*). Because of its artificial character the personal equation of investigator as well as that of the patient leads to great fluctuations in the percentages of frequency obtained. In 200 chiefly healthy subjects the author could not obtain a single positive result. On the other hand, out of 500 dispensary patients Falk obtained 23 pronounced results. If a blunt instrument is pressed upon the skin of a healthy subject and drawn in a line a white streak is produced as a result of mechanical anemia, which at once disappears. Shortly afterward a sense of constriction is felt and on inspection a second white line may be seen of variable breadth. This may persist unchanged for a time, and in any case vanishes by degrees. Is this a practically universal phenomenon? The answer must be doubtful. In a skin already pale it is difficult to produce. Hence the youthful, the brunette, the florid skin favor its production. If the maneuver is made with considerable force there appears at first a red streak—after an instant of initial anemia—which may show an outlying white zone. The latter soon vanishes, while the red streak may remain visible for an hour or more. These white and red streaks belong under dermographism, but not under urticaria proper—nevertheless, there is considerable confusion here, for some "lines" may ever so slightly project above the skin level. The author limits his study to these lines and their possible diagnostic value. He has devised special apparatus for bringing out the lines; he measures the time units, the degree of redness, etc. His results bear out the earlier claims made by Vulpian and Müller, and he has also accumulated a great body of data which are obtainable in normal individuals by varying external and internal conditions. He is disappointed in the negative results obtained in patients and pathological states, and believes that the method will have only physiological significance. In other words, in connection with various physiological studies of the vasomotor system, this form of dermographism may prove of scientific value.

May, 1917.

Dependence of Weight Increase on Season of Year.—Gripenberg weighed the patients in the Nummela Sanatorium during the different seasons and climatic variations. Other things equal, the average weight increase fluctuated notably during the course of weeks and months, so that in certain intervals there was loss in weight or weight was above the annual average. Loss in weight occurred chiefly in the winter and spring, gain in the summer and autumn. The average weekly weight increase is about constant in winter and summer; there is an increase in the summer which reaches a maximum in September and declines during the autumn. The curve of average increase of weight is almost the same as the curve of mean temperature, with this difference, that the maximum of the weight curve occurs two months later. The curves for deaths from tuberculosis and for new cases of the same shows the same behavior as the weight and temperature curves but is inverted.

Injury to the Eye from Iron Splinters.—Galetski-Olin reports on 58 of these accidents treated at the Helsingfors eye clinic during 1911-1915, inclusive: Diagnosis was made in 45 cases with the sideroscope alone, and in 28 by the latter and *x*-rays combined. In a few cases the giant magnet was used in diagnosis. In 16 cases removal of foreign bodies was effected with the giant magnet, while in 4 cases the latter failed. In 22 cases the electromagnet was successful alone, and in 7 others both magnets contributed to the positive result. The cornea was perforated in 37 cases, the sclera, while in 2 the junction was the site of the trauma. In the great majority of cases the splinter was found in the vitreous, retina and choroid.

Hygiea.

Case of Idiopathic Choledochus Cyst Treated by Operation.—Waller reports the following: girl, aged 10 years, subject for past 7 years to abdominal pain. Recently acutely ill with pains over gall bladder region, vomiting, subicterus, fever. There was fist-sized resistance in right hypochondrium. Operation showed gallbladder normal, and an elastic mass, retroperitoneal, partly covered by transverse colon and duodenum. Suspicion of hydronephrosis. Tumor ruptured during manipulation, with escape of 200 c.c. clear, dark-green bile. Cyst proved to be a greatly dilated choledochus. A sound introduced into the site of the rupture passed through Vater's papilla into the duodenum. The stump of the cyst was sutured in situ and a choledochoduodenostomy established. Smooth healing. Patient normal one year later. The number of cases of choledochus cyst previously on record was 34. The condition is believed to be congenital.

Optometric Ambulance.—Ginestous gives a description with diagrams of an automobile equipped for testing refraction. It is necessary to test visual acuity at the front. The vehicle contains a dark chamber, test type, glasses, diploscope, perimeter, etc.—*Le Progrès Médical.*

Restrictions in Use of Saccharin.—A commission has reported that the use of saccharin should be absolutely forbidden in children under 15 years of age, the old and invalid. In prescription work and pharmacology it should never be substituted for sugar. It must never replace sugar in foods which depend on the latter for nutritive value.—*Le Progrès Médical.*

Book Reviews.

THE PRACTICAL MEDICAL SERIES. Comprising 10 Volumes in the Year's Progress in Medicine and Surgery. Under the general editorial charge of CHARLES L. MIX, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Vol. I. GENERAL MEDICINE. Edited by FRANK BILLINGS, M.S., M.D., Head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago, assisted by BURRELL A. RAULSTON, A.B., M.D., Resident Pathologist, Presbyterian Hospital. Series 1917. Price, $1.50 per volume. Chicago: The Year Book Publishers.

THE volume on General Medicine in the Practical Medicine Series covers a great deal of very interesting work. The war reports are most freely quoted on trench fever, its symptoms, possible etiology, bacteriology, renal functions, and on irritable heart. The report from the Military Hospital at Hampstead, England, is very suggestive, not only as a study of diagnosis, but also of treatment by simple, systematic, graded exercises. There is much excellent work on tuberculosis. Among other careful studies is that on fractional gastric analysis, showing a "definite downward progression in both the mobility and the secretory function of the stomach from the very beginning of the disease. That hyperacidity with symptoms occurring in early stage and described by previous writers as common is quite rare. That even hyperacidity without symptoms is rare." This is only one of the places where fractional gastric analysis has proved or will prove helpful in diagnosis and intelligent treatment.

Diabetes and nephritis are both represented by large sections, as work along these lines is very active. The book is an excellent review of the year's progress.

COMPENDIUM FOR MEDICAL OFFICERS. By GILBERT E. SEAMAN, M.D., F.A.C.S., Major and Chief Surgeon Wisconsin National Guard. Madison, Wis.: Cantwell Printing Co., 1917.

THE new members of the Medical Reserve Corps are in need frequently of information with regard to their duties, for many of them have received but little training in the military service. A great many medical officers from the country will soon be going to the front and a book such as the one under notice, which contains the essentials of information required by those serving with troops, particularly in the zone of advance, should be extremely useful. The information given is of an eminently practical nature, and is detailed in concise form.

Among the chapters to be particularly recommended is that on the physical examination of recruits, for as is pointed out, the efficiency of a military force depends upon its "man power," upon the physical and mental make-up of the individual soldier. Consequently, the examination of the recruit should be thorough.

Perhaps, on the whole, the most important part of a medical officer's duty is that of sanitation. He must be acquainted with modern scientific sanitation in all its details. On this matter Dr. Seaman gives definite and valuable information. The duties of medical officers at the front are also well set forth, and a very excellent and full description is given of the most recent treatment of infected wounds.

The book is what its title implies—a compendium for medical officers and, moreover, a very satisfactory compendium.

THE PSYCHOANALYTIC METHOD. By Dr. OSKAR PFISTER, Pastor and Seminary Teacher in Zurich. Authorized translation by Dr. CHARLES ROCKWELL PAYNE. Price, $4.00 net. New York: Moffat, Yard & Co., 1917.

OF all the claims made by the psychoanalytic school, the assertion that the method is of value to pedagogy and theology is perhaps the most worthy of consideration. Some hold that by the proof or lack of proof of this claim psychoanalysis will stand or fall. At any rate this book, written by a teacher and clergyman, presents a very full account of the application of psychoanalysis to the problems of the personality which are brought to the confessor or to the teacher who plays the part of confessor so often. There are brief introductions by Freud and G. Stanley Hall. The author gives an extremely lucid, concise presentation of the theory of psychoanalysis, followed by an exposition of its technique which we do not believe is surpassed in English. Throughout the book Pfister is ever ready with apposite illustrations drawn chiefly from his own experiences; he has the true teacher's gift of presenting theories in a clear manner, elucidating them satisfactorily and then illuminating them by an appropriate example. Dr. Payne's translation is admirable.

THE TREATMENT OF TABETIC ATAXIA BY MEANS OF SYSTEMATIC EXERCISE. By Dr. H. S. FRENKEL, Medical Superintendent of the Sanatorium "Freihof" in Hieden (Switzerland). Second revised and enlarged English edition by L. FREYBERGER, J.P., M.D. (Vienna), M.R.C.P. (Lond.), M.R.C.S. (Eng.), Barrister-at-law of the Middle Temple, etc. With 130 illustrations. Price, $3.00 net. Philadelphia: P. Blakiston's Son & Co., 1917.

DR. FRENKEL'S excellent work on the re-education of tabetics is too well known to require extended mention here. The present handy little volume makes it readily available to American and English readers. The book is divided into three parts, a brief consideration of coordination and ataxia, a description of Frenkel's exercises occupying most of the volume, and a short discussion of the medical treatment. The exercises themselves are invaluable and give worth to the whole book; the illustrations, too, are numerous and complement the text neatly. Unfortunately, although the preface states that the work "is not a translation of Dr. Frenkel's book, but an adaptation of it," and that idiomatic difficulties have made it necessary to translate very freely and the translator's preface states that the text "has been thoroughly revised, redundances removed," and so on, the result has not been a smooth English exposition of the subject, but a text full of grammatical errors, solecisms, improper punctuation and awkward expressions. Many typographical errors which should have been caught up in the proof-reading, obtrude themselves upon the reader, *e.g.* the book begins "In Tabes Corsalis (!)" Another fault is that while the translator's preface practically concedes the fact that recent discoveries have established the syphilitic etiology of tabes, the part of the text dealing with the medical treatment advises finding out whether or not there is an antecedent syphilis before beginning treatment.

We commend this book as a very valuable one to the practitioner and to the neurologist, but we hope that the third edition will be more carefully revised before going to press.

REST, SUGGESTION, AND OTHER THERAPEUTIC MEASURES IN NERVOUS AND MENTAL DISEASES. By FRANCIS X. DERCUM, A.M., M.D., Ph.D., Professor of Nervous and Mental Diseases in the Jefferson Medical College, Philadelphia; ex-President of the American Neurological Association, of the Philadelphia Neurological Society, and of the Philadelphia Psychiatric Society; Foreign Corresponding Member of the Psychiatric and Neurological Society of Vienna; Member of the Royal Medical Society of Budapest; Consulting Neurologist to the Philadelphia General Hospital, etc. Second edition. Price, $3.50 net. Philadelphia: P. Blakiston's Son & Co., 1917.

THE attitude of this book may be typified by quoting a sentence from page 176: "This procedure (sterilization of the insane), to which there seems to be no valid objection, is, however, far from meeting with general approval, and at present there is no other way of dealing with the problem (the prevention of insanity) than that of institutional isolation." Under the general heading, "Suggestion by Magic and Mystic Practices," the author includes psychoanalysis and makes a strong attack on it. The following sentences may be quoted: "Psychoanalysis is an outcome of the general mystic tendency of the modern world." "To the jaded and blasé psychopathic patients . . . psychoanalysis presents something new, something interesting, something pruriently exciting." The book is divided into three parts, Rest, Therapeutics of Mental Diseases, and Suggestion. The first part is given the most space and suggestion is the next in bulk. Under the latter head are discussed such subjects as pythonism, magnetism, mesmerism, etc. The book is a large one, but printed on light paper, so that it is not too bulky. The print is clear and the index very complete.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SURGICAL SECTION

Stated Meeting, Held April 6, 1917.

DR. JOHN DOUGLAS IN THE CHAIR.

Posterior Dislocation of the Second Row of the Carpus.—Dr. RICHARD DERBY presented these cases. He stated that posterior dislocation of the second row of the carpus had been described by Cotton as "Dislocation of the Distal on the Proximal Row" and by Mayersbach as "Intercarpal Dislocation." Dr. Derby stated that he believed, as did Destot, that this form of dislocation was of far commoner occurrence than the literature would lead one to suspect. Besides the authors who he had quoted he could find no other mention of the condition, yet in looking over some *x*-ray plates of dislocations about the wrist he found, in addition to the two cases he was reporting, still another case of a similar dislocation. He believed that the dislocation of the second row upon the first was always posterior. Destot had described an anterior dislocation of the first row, but it occurred in a case of tuberculosis of the carpus. This form of dislocation migh result from severe falls on the hand in extension or, as on one of the cases presented, through forced rotation and hyperflexion of the wrist. A fracture of the scaphoid was often associated. The appearance which such a dislocation gave was a slight backward displacement of the hand, or in other words, a silver fork deformity at a lower level than it usually occurred. The second row of the carpus could be felt beneath the skin of the dorsum of the hand, and anteriorly a depression below the semiolunar made it possible to feel the sharp lower extremity of the palmar surface of this bone.

CASE 1—Dr. Derby stated that this patient, a man 24 years of age, a brakeman, was thrown from the top of a freight car by the sudden jolt of the engine and sustained a fracture of the left clavicle and an injury of the left wrist. At that time he was treated for a fracture of the styloid process of the left radius. The patient came under Dr. Derby's care on January 5th, at which time the appearance of the wrist was as described. No extension was possible and only about 10 degrees flexion. The *x*-ray showed a posterior dislocation of the second row of the carpus and a fracture of the styloid of the radius and of the scaphoid. On January 19th, under ether, all attempts at reduction proving futile, the semilunar, upper portion of the scaphoid and head of the os magnum were removed through a dorsal incision before reduction could be effected. A sugar tongue splint was applied for five days, when it was removed and massage and movement begun. The result at the end of two and one-half months was not good, but, as Cotton pointed out, the results were very tardy in radical wrist excisions.

CASE II.—Dr. Derby presented this patient, a young man, 23 years of age, who while fooling had had his left arm twisted behind his back until he felt something snap. He experienced great pain and had no power in the hand. Dr. Derby stated that he first saw the patient eight days after the injury. Flexion at this time was limited to 45 degrees. There was a prominence on the anterior surface of the wrist and a diagnosis of dislocated semilunar was made. An *x*-ray taken at this time showed that instead of the semilunar being dislocated, the os magnum together with the other bones of the second row were dislocated posteriorly. On December 5th, under ether anesthesia, strong traction on the hand, with pressure upon the dislocated second row, brought about immediate reduction. As soon as the pressure was released the dislocation showed a tendency to recur. A sugar tongue splint was again applied together with a pad over the dorsum of the hand. After ten days this was removed and massage and passive motion were begun. The end result was excellent.

Double Femoral Hernia in a Man.—Dr. SETH M. MILLIKEN presented this patient, a sailor, 34 years of age, who had been operated upon in 1914 for a left inguinal hernia. In December, 1916, he presented himself showing a distinct hernia in the left femoral region. He was operated upon in January, 1917, for what was supposed to be a left femoral hernia, through a left rectus incision. When he got up from this operation it was found that he still had a lump in the left femoral region and also one on the right side. He was operated on in February at which time a straight sac about the length of a finger was found on each side. There were no traumatic adhesions. Suture of Gimbernat's to Cooper's ligament gave a strong closure. The man was now able to perform hard work. The case was reported because double inguinal hernia was considered a rather rare occurrence.

Anterior Dislocation of the Hip.—Dr. SETH M. MILLIKEN presented this patient. He stated that the case was the first anterior dislocation of the hip that he had seen. The dislocation was the result of a collision with a moving truck and the patient had no idea of the direction of the force that produced the injury. He also sustained contusions of both legs and the left side of the abdomen. There was about 70 degrees flexion with eversion. The leg could be brought down to about 60 degrees, but the eversion could not be lessened. A small mass was felt to the left of the perineum. The dislocation was reduced by traction in the line of the femur and then the leg was brought down in extension and the head of the femur slipped easily into its socket. It was now five weeks since the accident and the patient had had no further trouble from the dislocation, though the contusions of the legs were still apparent.

Dr. KENNETH BULKLEY asked Dr. Milliken whether it would not have been better to have converted the anterior dislocation into a posterior one and then to have effected the reduction. Dr. Bulkley said he had three cases of dislocation of the hip, all of which had been easily reduced by Cotton's method of reduction.

Dr. MILLIKEN, in closing, said he thought it was a difficult matter to convert such an anterior dislocation into a posterior dislocation without carrying it through the capsule. He had been unable to get any description of the direction from which the violence causing the injury had come. Cotton said an anterior dislocation ought not to be made posterior before attempting to reduce it.

Perforated Gastric Ulcer.—Dr. JOHN F. CONNORS presented this case. He stated that the patient presented himself on Feb. 28, 1917, with a typical history of gastric ulcer. He did not show the case as an instance of a cure of perforated gastric ulcer, but because in discussing gastric ulcer he had been criticized because he had said it was useless to perform a gastroenterostomy. There was induration for about one and one-half inches about the ulcer and he had never seen a pylorus so thoroughly included as in this case in order to close over the wound. This case proved very conclusively that it was useless to do a gastroenterostomy. A man came under his observation who five or six years ago had had a gastroenterostomy performed. He recently died of nephritis and at post mortem no signs of ulcer could be found.

Sarcoma of Small Intestine.—Dr. CONNORS also presented this patient. He stated that the patient's condition had been diagnosed clinically as appendicitis, but he had been unable to confirm this diagnosis and decided to wait a while before operating. The patient vomited very persistently and he decided that intestinal obstruction was present. At operation he found an intussusception at the middle of the ileum and he also found a mass by the side of the intussusception. He did a resection and an anastomosis. Before entering the hospital the patient's weight had gone down from 135 to 90 pounds. After leaving the hospital his condition improved and he was able to go back to work. In February the patient returned to the hospital complaining of stabbing pains in the abdomen and attacks of vomiting. The speaker at first thought his trouble was caused by adhesions at the site of the former operation. However, the patient's condition became so precarious that it was decided to operate. The adhesions at the site of the old scar were very slight at the upper edge and there was only a very narrow strip that looked like a thin piece of fascia around the old scar. He found round celled sarcoma present and secondary metastases like the growth removed at the former operation.

DISCUSSION OF DR. CONNORS' CASES

Dr. WILLIAM H. LUCKETT said that in connection with Dr. Connors' case of sarcoma he would like to show a specimen of sarcoma of the cecum which had been removed from a little child eleven years of age. The child was operated upon after having given a distinct history of two separate attacks of appendicitis by another doctor. The first attack was accompanied by vomiting and chills, but very little rise in temperature. In a week he had another attack accompanied by abdominal pain and a temperature of 102° F. At operation a distinctly gangrenous appendix was found and the abdomen was full of enlarged mesenteric glands, and it was thought that the patient had tuberculous peritonitis. No attempt was made to remove these glands. About a month later a mass was palpated in the left hypochondrium. At operation the belief was still held that they were dealing with a tuberculous condition and he had been particularly careful to point out the typical small tubercles on the parietal peritoneum. Eight inches of the ascending colon and ileum were resected. The mass removed was found to be a polymorpho-cellular growth. This growth must have been a metastasis from the sarcoma. Several of the mesenteric glands showed the same time of growth as in Dr. Connors' case.

Dr. FENTON B. TURCK said that these cases of perforation in which recovery took place were of special interest. Richardson had pointed out that in a great number of cases perforation of a gastric ulcer took place, a simple suturing of the perforation was done and there was never a return of the ulcer: he concluded from this that immunity had resulted from the expulsion of the stomach contents into the peritoneal cavity. If immunity had occurred in such instances there must be something more involved in the production of ulcer than the mere mechanical factors. Dowden pointed out that in over 40 per cent. of the cases of duodenal ulcer there was a history of previous infection and in over 80 per cent. there was a long history of intestinal stasis and constipation. The speaker's own experiments showed that the intestinal flora played an important part in the production of ulcer. The presence of pepsin or of strong acid gastric juice had but little influence in the production or continuance of ulcer as shown by Mann, who implanted the mucus membrane bearing ulcer into the gastric wall and no injury resulted; the lesions promptly healed bathed in gastric juice. The reason ulcers occur in the pyloric-duodenal region was that the antibody ferments were stronger in this region than in any other segment or level—that was also why death occurred in high loop obstruction. The antibodies being more powerful caused more split products to form. Burge had shown that there was a lack of oxidation of the tissue cells that led to ulcer and that was responsible for the cytolytic action. The empirical facts presented by Dr. Connor that ulcer healed when immunity was established after merely closing the perforation would suggest to the surgical mind the value of producing immunity in ulcer before perforation had taken place in all ulcer cases.

Echinococcus Cyst of the Liver; Complete Excision.—Dr. KENNETH BULKLEY presented this patient, a young man, 21 years of age, who was admitted to the Cornell Division of Bellevue Hospital in January, 1917. The patient gave a history of malaria three years ago, and two years ago had an attack of jaundice at which time a lump was observed in the right epigastrium. This lump had persisted for two years, during which time the patient had suffered with gastric distress after eating and constant pain radiating to the back. He had a pulse of about 40, a negative Wassermann, and a leucocyte count of 16,000. The *x*-ray examination was negative except that the liver seemed to be enlarged downward. The mass extended from the costal margin to the umbilicus and seemed about six inches in width. The diagnosis lay between echinococcus cyst and hydrops of the gallbladder. At operation a cystic tumor was found partially covered by the right lobe of the liver. A complete excision was done. Technically the removal of the cyst was not difficult. The specimen removed proved to be an echinococcus cyst. Dr. Bulkley exhibited lantern slides demonstrating the pathology of the specimen.

Dr. W. H. LUCKETT said he also had a specimen of echinococcus cyst of the liver, which had been removed five years ago and each time he looked at it more of the cysts had ruptured. The patient from whom the cyst had been removed was 19 years of age and gave a distinct history of intermittent jaundice. Before operation the case had been diagnosed as one of hydrops of the bladder; at operation they found this echinococcus cyst of the liver. The presence of an echinococcus cyst had been considered as a possibility. But about two years previously he had had an echinococcus cyst in which fremitus was easily elicited and as they could not hear anything in this instance they had decided that it was not an echinococcus cyst. The cyst was entirely within the liver and they were unable to make a complete enucleation. Enucleation was made excepting at one point at which they sutured together the heads of the mother cyst after making a free incision and scooping out the contents of the cyst. This case had been described before. A writer in Australia had mentioned a typical urticarial rash which should make one suspicious of echinococcus cyst. A most interesting point in connection with those cases was that they all occurred among the very poor. This patient gave a history of having eaten frozen uncooked pork over a considerable period of time. She made a complete recovery.

Dr. WILLY MEYER said he had had a case of echinococcus cyst of the liver which he had operated on three or four years ago. In this instance the cyst was incised and the walls stitched to the peritoneum and for three or four weeks afterward the contents of the cyst were discharged through the wound and then the wound healed up.

Dr. DOUGLAS stated that he had seen a case at Bellevue Hospital last summer in which the patient showed marked jaundice with temperature elevation and it was thought might have cholangitis. Operation showed a very large gallbladder and an enormously distended common duct. There seemed to be nothing the matter with the pancreas and no stones were present. A mass was palpated in the left lobe of the liver beneath the ensiform cartilage which was thought to be an abscess. At operation the gallbladder was drained and a separate incision was made for the purpose of draining the supposed abscess after adhesions had formed. The contents of the cyst that was later evacuated showed hooklets under the microscope and made it evident that he was dealing with an infected echinococcus cyst. This patient made a good recovery. The obstruction of the common duct was due to the pressure of the mass in the left lobe of the liver on the common duct.

Dr. BULKLEY said that Dr. Luckett spoke of fremitus as a sign of diagnostic value in echinococcus cyst. Fremitus was present in only about 50 per cent of the cases. No fremitus could be demonstrated in the case reported. Urticaria had also been mentioned; this occurred only when there was rupture of the cyst. If jaundice was associated with echinococcus cyst it was probably the result of pressure. Echinococcus cyst was not usually due to eating raw pork, it was supposed to be conveyed by the excreta of dogs and had been explained by the fact that vegetables might become contaminated with the excreta.

Thromboangiitis.—Dr. CHARLES GOODMAN presented a report of six cases to show some of the phases of the clinical picture of the later stages of the disease. The first case presented a trophic ulcer between the 4th and 5th toes with occlusion of the tibial arteries. The second patient had been submitted to a series of amputations of the toes and eventually the foot was amputated. His pain, however, had not been relieved. The third case was of interest because the disease began in his right upper extremity with the appearance of trophic ulcer on his index finger. This had healed but he has a very small radial pulse in this extremity. He had his left leg amputated below the knee on account of gangrene, but the wound has failed to heal and an amputation of the thigh would be necessary. The fourth case was one which showed temporary amelioration of the symptoms following the ligation of the femoral vein. Two other cases were shown. One with both lower extremities amputated and the fingers of one hand, while the other had had

all four extremities amputated for this disease. This patient had a very satisfactory prosthetic apparatus which enabled him to become remarkably proficient in writing. Most of the cases proved that the condition was bilateral and progressive. Dr. Goodman expressed the opinion that when amputation became necessary the only logical operation was an amputation at the thigh in order to obviate the pain incident to this condition and to avoid the distress of successive operations.

Thromboangiitis.—Dr. WILLY MEYER presented a number of cases showing the results of arteriovenous anastomosis, ligation, and amputation in thromboangiitis. The first patient was a young man whom Dr Meyer had shown before and he now presented him to show the results of arteriovenous anastomosis at the end of four years. The man was operated upon in May, 1913, when he was 30 years of age. At that time he had gangrene of the big toe and all the typical signs of thromboangiitis. Dr. Meyer said that personally he was in favor of conservative surgery and hesitated to do an amputation at the hip in this case. He therefore made an incision in Scarpa's triangle and did an arteriovenous anastomosis as he had described before. There was no great amount of bleeding. He could feel the thrill in the vein eleven days after the operation. In a short time there was bleeding of the toes and it became necessary to apply a number of ligatures. This patient had been shown before the Surgical Society in 1914 and before this Section in 1915 and it was now interesting to see the results at the end of four years. The patient was now in apparently perfect health. He stated that walking tired him. This was one instance in which arteriovenous anastomosis had given an excellent result but he did not believe that this man was cured of the fundamental cause of his disease. The man, however, had been in a serious condition such as ordinarily demanded amputation and was now able to be about and was apparently well. When operative interference became necessary, the first step was ligation at the point of Scarpa's triangle. If this did not relieve the patient and the disease was progressive, the second procedure was to perform an arteriovenous anastomosis with the best possible technique. If this did not serve to relieve the patient the third step was an amputation, done as conservatively as possible. Dr. Meyer said he did not have a paper but wished to discuss several theories in reference to the etiology of thromboangiitis. He said that "thromboangiitis" was the name given to the condition under discussion by Dr. Leo Buerger who had studied its gross pathology, had made microscopical studies of the occluded vessels, and had shown conclusively that disease of the vessel walls was present and occurred not in the small capillaries but in the small vessels proximal to the capillaries and had many of the characteristics of an infectious disease. In a paper on this subject, read in November, 1915, and published in the Annals of Surgery, he had expressed the opinion that thromboangiitis might be a disease of the blood itself or a combination of blood and blood vessels disease. Today, Dr. Meyer said, he felt convinced that it was a blood disease and that the findings in the blood vessels were secondary, being the result of the changes in the blood. According to his theory thromboangiitis was diametrically opposed to hemophilia. If they thought of the pendulum of a clock swinging from one side of the arc to the other, they might write on one side of this arc hemophilia and on the other thromboangiitis. Indeed, this disease might better be spoken of as "thrombophilia." It was now known that hemophilia was a disease of the blood platelets. It had been shown that in hemophilia there was an insufficiency of thrombokinase as compared with normal blood or else the thrombokinase was combined in such a way that it could not be given off easily. Now he believed that thrombophilia was also a disease of the blood platelets and that here they had the opposite condition, an excess of thrombokinase in the blood, imparting to the blood a tendency to clot more readily. In the next place it had been found that hemophilia was found in the male and not in the female. The female might transmit this condition to male offspring but did not have it herself. In thrombophilia we found this same phenomenon. This brought one to the question of what determined sex in the male and the female and to a consideration of the part played by the ductless glands. It seemed that either the internal secretion of the male was increased or decreased, or there was a change in the quality of the secretions, while the female sex was protected by some secretion which the male did not possess; this was most likely the ovarian secretion. These secretions entered the blood and it seemed quite probable that the diseases under consideration were the result of the reaction of the blood to these secretions. Dr. Meyer stated that when he had tried to find something else besides surgical treatment for this condition and decided to try hyperdermoclysis as a conservative measure. They had made a study of the blood and had tried transfusion in three cases. In one instance they had to examine the blood of 38 persons, in the second case 40 persons, and in the third case 50 persons, before the proper donor could be found. But he found that the blood that fitted one of these patients fitted all three. This was a remarkable observation and it could not be explained except on the theory that the cause of the disease was in the blood proper. Dr. Meyer also advanced a theory to explain why thromboangiitis started in the small vessels and not in the capillaries. He spoke of the prevalence of the disease in Russia, Poland, Galacia, Roumania, Serbia, etc., and of the statement that it affected more particularly Hebrews. We had evidence to show that it had existed for centuries. It was found among people who for generations had been underfed and underclothed and who had for centuries intermarried. It thus seemed that thromboangiitis might be a form of degeneration affecting one or more of the correlated glands of internal secretion. In the elucidation of the problems connected with this disease it was most difficult to find our way, since thromboangiitis could not be produced experimentally thus far in animals. If this were possible they might hope to get knowledge that would enable them to treat this condition so that they would not be confronted with such a spectacle as they had witnessed this evening as a result of surgical interference and successive amputations in these pitiable people. This was far too big a problem for one man or one group of men. Efforts should be made to impress some great philanthropist as to its importance and have him endow a commission and appoint medical men to investigate this problem as had been done in the case of pellagra. Although this disease was not as widespread as pellagra, one would find these victims of successive amputations in all large cities in considerable numbers, so that it was well worth while searching for the cause of this disease.

Dr. CHARLES GOODMAN said there were three points regarding thromboangiitis which he wished to take up for discussion. In the main, he was in accord with the statements made by Dr. Meyer in his masterly presentation. In the light of recent research and conclusions drawn from personal observation of over 300 cases of thromboangiitis during a period of over twenty years he was of the opinion that we had, up to the present time, no known methods that would result in a *permanent* cure of the disease. When the palliative measures enumerated tonight failed to give relief a surgical procedure such as ligation of the femoral vein as described by Oppel or an arteriovenous anastomosis between the femoral artery and vein performed in properly selected cases was more likely to prolong the life of the limb than any other measure at our command. In the presence of gangrene in a case of thromboangiitis he was inclined to recommend to the patient a high amputation as the most logical procedure for his relief. Dr. Goodman said he would like to correct the generally accepted view on the epidemiology. The majority of cases seen in this city had been among the poor Jewish immigrants from Russia and Gallacia and other regions where typhus fever was endemic. Some writers had expressed the belief that the disease was peculiar to the Jewish race, but this was a misconception as was evidenced by the fact that thromboangiitis was seen in countries in which typhus fever was epidemic and endemic irrespective of the ethnic composition of the population. A review of the literature revealed

clearly that presenile gangrene of the extremities was encountered in almost every civilized country but was more prevalent in those countries where typhus fever was epidemic, as in Russia, Austria, Japan, Turkey, and Bulgaria. For a number of years the speaker stated that he was inclined to accept the prevailing opinion that cigarette smoking entered largely into the etiology of the disease, but while a large majority of the patients gave a history of cigarette smoking there were thousands in this country and elsewhere who were inveterate smokers and did not acquire this disease. Moreover, individuals afflicted with arterial disease, the result apparently of chronic alcoholic intoxication, did not manifest this disease. Syphilis as an etiological factor could be excluded by the fact that in the series of cases which he had studied the Wassermann reaction was almost always negative. This was in accord with the results of Buerger and Kaliski. Disturbances of metabolism could likewise be excluded as shown by studies made at Beth Israel Hospital. The etiological relationship of thromboangiitis to typhus fever had been noted as far back as the seventeenth century. Several authors writing in recent times had suggested that thromboangiitis was caused by some pathogenic organism, but they had not brought forth any proofs in substantiation of their contentions. Dr. Goodman said he had been fortunate enough to have presented about a year ago (Meeting of the New York County Medical Society, March, 1916) what appeared to him to be conclusive proof to the effect that the virus instrumental in causing typhus fever was responsible for the morbid condition of the extremities which was called thromboangiitis.

The reports of the Bulgarian campaign bore out his contention that thromboangiitis was of infectious origin. Professor Zinsser of Columbia University had informed the speaker that a number of cases of gangrene of the extremities were seen by him during his recent visit to Serbia. Emil Wiener, after the examination of a considerable amount of postmortem material, stated that the most characteristic pathological evidence of typhus was the extreme fragility of the vessel walls. This might entail thrombotic formation in the vessels of the lower extremities and elsewhere. E. Fraenkel and Jochman supported this evidence with reference to the condition of the walls of the arteries. Dr. Shattuck of Boston, who had just returned from abroad, stated that gangrene of the feet seemed to have been very common during the cold months in the early part of the epidemic of typhus. He mentioned that Drs. Strong, Maitland, and Moore had made similar observations and stated further that Moore was of the opinion that the gangrene was in all probability brought about by arterial thrombosis and agreed with Maitland in considering exposure to cold as being a contributing factor. It was reasonable to presume from the reports and observations cited that typhus virus had a special predilection for the blood vessels, especially of the extremities, and that its activity was followed by an inflammation of the intima with the formation of the thrombi which was frequently followed by gangrene of the affected extremity.

Dr. Leo Buerger said that he was very much interested in Dr. Meyer's new theory, as to the proper genesis of the disease to which he had given the name, thromboangiitis obliterans. However, he did not believe that any definite pathological or experimental evidence had been adduced by the reader of the paper, the conclusions reached being based upon hypothesis and attempts to explain thromboangiitis by analogy. In the disease hemophilia there were no lesions suggestive of an inflammatory process. Before we could come to any reliable conclusions as to the etiology and pathology of thromboangiitis obliterans we must have a clear conception of the pathological lesions that had been already demonstrated both by examination of autopsy specimens, amputated limbs, and the results of biopsies on exsected veins afflicted with the acute phlebitis of the disease. Such studies had been made by Dr. Buerger, who found that not only the superficial veins but also the deep arteries might be demonstrated as the seat of an acute inflammatory process. The lesions of this process presented a specific microscopic picture, which had been regarded by him as a typical reaction on the part of the tissues, to either some toxin or some bacterial agent, neither of which had as yet been disclosed. Thus, in the superficial veins involved in the process of migrating phlebitis—which was but a part of the clinical picture of thromboangiitis obliterans—the so-called acute lesions of the disease had been demonstrated. In this the adventitia and the media were diffusely penetrated by polynuclear leucocytes, the lumen of the vessel being occupied by a mixed, for the most part, red clot. When the region of the clot was examined in given specimens, the various stages of the clot could be demonstrated. Early in the process miliary abscesses were found, usually in the peripheral portions of the clot, the pus cells forming which could be traced to an origin outside of the vessel, having migrated into the lumen of the vessel through the media and adventitia. These miliary abscesses underwent a specific type of organization, in the course of which the typical and characteristic picture of thromboangiitis obliterans was developed, namely, foci that looked to the casual observer very much like miliary tubercles. However, they contained endotheliod cells and giant cells. In his recent studies, however, on the acute lesions of thromboangiitis obliterans, Dr. Buerger had demonstrated that the giant cells were the results of abortive attempts on the part of angioblasts or vessels forming cells, otherwise called endotheliod cells, to vascularize the miliary abscess. Later on the pus cells disappeared and the miliary focus containing endotheliod cells and giant cells became converted into a sort of nodule. Such a picture was characteristic of thromboangiitis obliterans and upon its presence the diagnosis could be made. It was just as peculiar to this disease, as the picture in Hodgkin's or that of tuberculosis. In fact, in all of these diseases, the microscopic alterations were an expression of the peculiar reaction on the part of the tissues to some bacterial agent or some toxin. In short, in the face of these findings, it would be audacious for us to assume that we were dealing with mere thrombosis in thromboangiitis obliterans, as Dr. Meyer would have us believe. It was not merely a thrombophilia, or tendency to clot, that was characteristic of thromboangiitis obliterans, but an inflammatory process as well. Nor must we accept the theory that such lesions occurred as the result of mere clotting of blood, for Dr. Buerger's studies on thrombosis due to other causes had never disclosed the typical picture of thromboangiitis obliterans but had corroborated the findings of others whose descriptions of thrombosis and organization would be read in every text book.

As for Dr. Goodman's suggestion that typhus fever might be an etiological factor in thromboangiitis obliterans, Dr. Buerger's experience in taking histories of many recent cases had not revealed a single instance in which typhus fever had been present to the knowledge of the patient. In conclusion Dr. Buerger wished to point out that not only had their researches on the etiology, but also their experiments with the treatment of the disease, been fruitless for the reason that we were not for the most part recognizing the disease in its incipiency, that was, in its true stage, but were treating it and describing it when it had already reached the chronic or "healed" stage, in which the vascular occlusion had already become extensive, the vessels being filled with more or less organized clot. Under these circumstances, we were dealing with the mechanical disturbances of circulation, the results of a healed process, rather than the true disease itself.

Dr. William C. Lusk said he must take exception to the statement that they had run the whole gamut in the treatment of thromboangiitis, for in his experience there was one mode of treatment that had been effectual that had not been mentioned and that was electric baths. He had found electric baths had a very definite effect in relieving pain and improving the lesion when the process was not far advanced. The question of syphilis had not been brought out in connection with this disease. It was had disappeared as though by magic and had not reof particular interest that in six cases coming under his observation four gave a positive Wassermann.

In such cases antisyphilitic treatment was an important factor.

Dr. Henry W. Frauenthal said that since September, 1915, he had seen 171 cases of obliterating endarteritis at the Hospital for Deformities and Joint Diseases. Of this number, only eseven gave a Wassermann positive, while the other cases examined at the institution gave a Wassermann positive in from 15 to 20 per cent. of the cases. In the treatment of these cases no anodyne seemed to relieve the pain. Heat with a Tyrnauer baker gave little relief, while exposing them to the heat and light of electric light bath seemed to give a remarkable relief of pain which continued for some period of time. He had read a paper at the Budapest Congress in 1910 on the use of the electric light bath for the relief of pain and the arrest of the gangrene. That in one of the cases reported at that time who had not slept in bed for one year, and who was unable to sleep for more than one hour in the chair, having had the beginning of gangrene of the little toe: the gangrene had been arrested, the toenail had returned, and for the past seven years the patient had remained well. The patient's younger brother at the age of twenty-one had both his legs amputated above the knee for obliterating endarteritis. This patient had kept up treatment by the electric light bath and by exposing his feet to sunlight during the summer, which had prevented the progress of the disease. Only eight cases reported were not Russians. One patient seen in consultation with Dr. Willy Meyer, a gentleman associated with the Hospital for Deformities and Joint Diseases, had a beginning gangrene of his right toe, later of his left big toe, and under the electric light treatment, these had both healed up and remained well for a period of two years. A large number of these cases had been materially benefited by this treatment, although some had gone on to gangrene and required amputation. The conservative treatment by white light which had been used for over 500 patients had seemed the most efficient and lasting method.

Dr. J. Gottlieb said that in Dr. J. Shelton Horsley's paper, read before the American Medical Association at Detroit he expressed the same ideas that Dr. Buerger had expressed, that thromboangiitis was due to an irritability of the blood vessels and not a disease of the blood; that there might be a condition of the blood vessels similar to that in latent arteriosclerosis. We knew that arteriosclerosis might develop in individuals between the ages of 35 and 40 years and that there was not an actual inflammatory process present. He could not believe that the disease was of infectious origin, because he could not be convinced that there could be an infectious disease to which the female would be immune. He had not had experience with the ligation of the femoral vein but he could not understand how it could improve the condition.

As to amputation, Dr. Goodman had recommended high amputation; he had seen very excellent results from low amputation and also had seen some very good stumps and knew of cases going about in which good results had been obtained. He had been making studies along the same line as Dr. Horsley in order to determine whether the arterial blood when directed into the veins really reached the tissues for which it was intended. Dr. Horsley had shown that they did not get a permanent reversal of the circulation and that in no instance did the reversed circulation reach the foot. Dr. Gottlieb described experiments which he had made and illustrated them with *x*-ray plates, which showed that in no instance did ligation of the femoral vein force the circulation to a point anywhere near the foot; the peripheral circulation seldom went much below the knee and never anywhere near the foot. If, however, one ligated the superior femoral vein the circulation went to the tip of the toe.

Dr. S. J. Sinkowitz said that they had been trying Bier's suction hyperemia at Mount Sinai Hospital in the treatment of thromboangiitis and while they did not claim that it was curative it certainly relieved most of the symptoms. In some of the cases the pain had disappeared as though by magic and had not returned later, while in the majority of the cases the greater number of the other symptoms were very decidedly improved.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Pulmonary Tuberculosis. Its Diagnosis, Prevention, and Treatment. By W. M. Crofton, M.D. With colored frontispiece and twenty illustrations. 122 pages. Price, $1.50 net. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

The Practical Medicine Series. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the general editorial charge of Charles L. Mix, A.M., M.D. Vol. II. General Surgery. Edited by Albert J. Ochsner, M.D., F.R.M.S., LL.D., F.A.C.S. Series 1917. Published by the Year Book Publishers, Chicago, Ill. Price, $2.00 per vol. Price of a series of 10 volumes, $10.00.

Mortality Statistics, 1915. 16th Annual Report. Department of Commerce, Bureau of the Census. By Sam. L. Rogers, Director. 707 pages. Published by the Government Printing Office, Washington, D. C., 1917.

Impotency, Sterility and Artificial Impregnation. By Frank P. Davis, M.D. 138 pages. Published by C. V. Mosby Co., St. Louis, Mo., 1917.

The Secretion of the Urine. By Arthur R. Cushny, M.A., M.D., LL.D., F.R.S. 241 pages. Illustrated. Published by Longmans, Green & Co., London, New York, Bombay, Calcutta, and Madras. $3.00 net.

Erfahrungen uber Diagnostik und Klinik per Herzklappenfehler. Von Prof. Dr. S. E. Henschen. Mit 271 Kurven. 355 Pages. Price, $15.60. Published by Verlag von Julius Springer, Berlin, Germany. 1916.

Rational Sex Ethics. A Physiological and Psychological Study of the Sex Lives of Normal Men and Women, with suggestions for a Rational Sex Hygiene. By W. F. Robie, A.B., M.D. $3.50 net. Published by Richard G. Badger, Boston, Mass. Toronto: The Copp Clark Co., Ltd.

Some Personal Recollections of Dr. Janeway. By James Bayard Clark. 36 Pages. Price, $1.00. Published by G. P. Putnam's Sons, New York & London. The Knickerbocker Press. 1917.

The Treatment of Emergencies. By Hubley R. Owen, M.D. 12mo volume of 350 pages with 249 illustrations. Cloth, $2.00 net. Published by W. B. Saunders Co., Philadelphia and London.

Obstetrics and Gynecologic Nursing. By Edward P. Davis, A.M., M.D. 12mo. volume of 489 pages, 104 illustrations. Fifth edition, thoroughly revised. Buckram, $2.00 net. Published by W. B. Saunders Co., Philadelphia and London. 1917.

Diagnostic Symptoms in Nervous Diseases. By Edward L. Hunt, M.D. Second edition, revised. 12mo of 292 pages, illustrated. $2.00 net. Published by W. B. Saunders Co., Philadelphia and London. 1917.

1916 Collected Papers of the Mayo Clinic, Rochester, Minn. Octavo of 1014 pages. 411 illustrations. Published by W. B. Saunders Co., Philadelphia and London. 1917. Cloth, $6.50 net. Half Morocco, $8.50 net. Edited by Mrs. M. H. Mellish. Vol. VIII. 1916.

Glaucoma—A Handbook for the General Practitioner. By Robert Henry Elliot, M.D., B.S., Lond.; Sc.D., Edin.; F.R.C.S., Eng., etc. Illustrated. 60 Pages. Price, $1.50 net. Published by Paul B. Hoeber, New York.

Notes on Galvanism and Faradism. By E. M. Magill, M.B., B.S., Lond., D.P.H., R.C.S.I. (Hons.). With 67 illustrations. 220 Pages. Price, $1.50 net. Published by Paul B. Hoeber, New York. 1916.

Operative Surgery of the Nose, Throat, and Ear. By Hanau W. Loeb, A.M., M.D. In two volumes. Vol. II. 476 Illustrations. 427 Pages. Published by C. V. Mosby Co., St. Louis, Mo.

Experimental Pharmacology. By Dennis E. Jackson, Ph.D., M.D. With 390 original illustrations including 24 full-page color plates, and 535 pages. Published by C. V. Mosby Co., St. Louis, Mo. 1917.

THE U. S. PHARMACOPŒIA, IX.*

By HORATIO C. WOOD, JR., M.D.,

PHILADELPHIA.

JUST one hundred years ago last January, Dr. Spalding submitted to the Medical Society of the County of New York, a project for the formation of a National Pharmacopœia, as the result of which proposition a general convention was held in Washington in 1820 and the first U. S. P. was published in that year. This work was merely a list of the drugs which were deemed of sufficient importance, with directions for the manufacture of certain preparations made from them, and was the work solely of physicians. In 1840 the cooperation of colleges of pharmacy was requested and since then the apothecaries' share in the revision of the work has become so important that one often hears physicians declaiming that the Pharmacopœia is of no use to the doctor. Such a statement always makes me suspect that the speaker does not possess a copy of the Pharmacopœia and has never carefully perused it. While in modern commercial conditions the doctor is not directly interested in the details of methods of assay and tests of identity and purity, there is much matter in the Pharmacopœia with which he is immediately concerned. For myself I can only say that the Pharmacopœia is one of the most frequently consulted books of reference and always, I believe, with advantage to my patients.

To the up-to-date physician the appearance of a new revision of our national standard is an event of real importance. I am glad, therefore, of an opportunity to say a few words of some of the more striking changes in the latest edition which is deserving of commendation for its virtues both of omission and commission.

Let me briefly speak first of the things which have been left out. Most important among these are a lot of worthless herbs such as camomile, boneset, horehound, burdock, cypripedium, scutellaria, sage, pennyroyal, marigold, and other similar truck which has littered up our national standard for many years. There are a few of this class of drugs still retained as a sop to the superstition of a diminishing number of practitioners. While I shall be glad to see the last of them I am gratified to see that the present revision committee has succeeded in evicting so large a number.

Similarly pleasing, especially to those of us who have had to teach materia medica, is the fact that nine salts of iron have been dismissed. One could not say that these were worthless for they possess the therapeutic virtue of iron in general, but they were certainly quite needless as we still have ten preparations of this metal available. If perchance any of you have lost a pet form of iron you can find it by applying to the National Formulary.

An omission about which there has raged, and still is raging, an acrimonious discussion is that of the alcoholic beverages, wine and whiskey. Personally, I am convinced that, under certain circumstances, alcohol is a valuable therapeutic remedy but my belief in the medicinal usefulness of alcohol does not necessarily imply the necessity of a Pharmacopœial standard for whiskey. There were strong arguments brought forward in the discussion of this question in the committee on revision by both sides, but I think the reasons which finally resulted in its deletion were, first the divergence of opinion as to the reliability of certain tests for differentiating artificial from natural whiskey; secondly the fact that the U. S. Government has a standard for labeling whiskies and their imitations independent of that of the Pharmacopœia, and that if the Pharmacopœial standard differed from that of the Department of Agriculture it would be commercially unenforceable. I was much struck by the remarks of Dr. Osborne in this connection, who said that if we wanted to obtain the therapeutic action of alcohol and stick to pharmacopœial preparations, we had such a whole host of available substitutes in such mixtures as tincture of gentian, compound tincture of cardamon, aromatic elixir, etc. We are sometimes prone to forget that we can obtain all the action of alcohol by administering alcohol. It is not necessary to drink whiskey to become intoxicated.

More interesting than the deletions, however, are the innovations. Perhaps the most important of these is the official recognition—for the first time, I believe, in the history of the world, certainly in the history of this country—of physiological standards for such drugs as digitalis, cannabis indica, hypophysis, and suprarenal. In the cases of aconite, digitalis, strophanthus, squill, and suprarenal the biological standard is advised, but is made compulsory only in the cases of cannabis and solution of hypophysis. Some may question what is the advantage of a standard which is not compulsory. The advantage lies in the fact that manufacturers can no longer advertise their compounds as biologically assayed unless they conform to the Pharmacopœial requirements as to potency. Hitherto certain manufacturers have put upon the market preparations of digitalis or other drugs which were claimed to be physiologically standardized but the standard for whose activity was any indefinite

*Read at a meeting of the American Therapeutic Society, June 1 and 2, 1917.

degree of potency that happened to suit their whims. Now a preparation which is physiologically standardized must conform to the requirements of the Pharmacopœia.

Among the newer synthetics which have won for themselves an important place in our armamentarium several have achieved official recognition, although, regrettably, some have been omitted through fear of legal complications on account of protecting patents. Of those which have been admitted I may mention first two morphine derivatives, ethyl-morphine, and diacetyl-morphine. Let me beg of you to forget the trademark names for these two popular and valuable drugs. Of the value of these drugs and the range of their usefulness it is hardly necessary for me to speak. I might, however, point out that they differ considerably from each other and from their common ancestor morphine. The diacetyl-morphine is, both relatively and absolutely, much more actively depressant to the respiratory center than is morphine. Because of its absolutely greater power it must be given in much smaller dose and because of its relatively greater sedative effect upon respiration it is of much less value as an analgesic than morphine. In cases where an effect upon respiratory function is desired, as in excessive cough, or especially in bronchial asthma. I think the diacetyl ester is generally to be preferred to morphine as being not only more certain but, in the doses required, less disturbing to the alimentary canal. Ethyl-morphine, on the other hand, is distinctly less active than morphine and more closely resembles codeine, which is a methyl-morphine, than it does the mother alkaloid. In my own experience it has seemed to possess greater anodyne properties than either codeine or acetyl-morphine, although of course greatly inferior to morphine. It has the very great advantage, however, that there is much less danger of habit formation from its use; in fact I have never heard of a case of habit from either ethyl-morphine or codeine.

A much less widely known novelty is sodium perborate. This superoxygenated compound in aqueous solution yields up an atom of oxygen which unites with the elements of water to form hydrogen dioxide, and leaving behind the alkaline sodium pyroborate, not the sodium borate of the Pharmacopœia, commonly called borax. Because of the alkalinity of the solution formed the hydrogen dioxide is rapidly decomposed with the evolution of oxygen. This salt offers a means of preparing extemporaneous solutions of peroxide of hydrogen. Seventy grains of sodium perborate to an ounce of water gives a solution about equivalent in antibacterial properties to the official solution of hydrogen dioxide; for convenience of remembering we may say to use from one-half to one drachm per ounce. The solution must be freshly prepared immediately before use.

Solomon is supposed to have remarked that there was nothing new under the sun, and the present fashion in laxatives is an illustration of his perspicacity. Some thirty years ago Dr. Randolph of Philadelphia recommended the use of petrolatum in the treatment of chronic constipation. He had quite a number of followers in this use and for a short time the drug enjoyed considerable popularity, and then we all forgot about it until Sir Arbuthnot Lane introduced the use of the liquid petrolatum, or as it is popularly called, mineral oil, for the same purpose. The effects of petrolatum, whether in the liquid or semisolid state, are essentially identical. Namely, it gives a soft, indigestible, but inoffensive material to lend bulk to the passages and perhaps may have some lubricating effect. There is a common belief that the more viscid mineral oils are less prone to ooze out through the sphincter ani, and the Pharmacopœia has therefore recognized two forms of liquid petrolatum, a light one intended for use in atomizers, and a heavy viscid oil for internal use. If there be any truth in this idea that the more viscid oils are to be preferred for this purpose it would seem rational to go back to Dr. Randolph's custom and use the semisolid rather than the liquid petrolatum.

Incidentally it is interesting to note how fashions in laxatives, as in clothes, change for no apparent reason except the whims of the medical public. When the committee on revision began its work agar-agar was enjoying its brief period of reclame as the *ne plus ultra* for the mitigation of sluggish colons, just as to-day does liquid petrolatum. This cellulose-like extract of Japanese sea weeds acts because, like petrolatum, it is entirely unaffected by the digestive juices and passes through the intestinal tract unabsorbed. By virtue of its own bulk, but especially because of its power of holding water, it gives mass to the contents of the colon. So fleeting are fashions, however, that this drug, which was in the zenith of its popularity at the beginning of the work of revision, had almost passed from notice before the Pharmacopœia appeared. While speaking on the subject of laxatives I may call your attention to the fact that phenolphthalein, which had long been considered in the appendix of the Pharmacopœia only as a test for alkalies, has now been moved to the body of the book because of its popularity as a cathartic.

A very interesting addition is phenylcinchonic acid which was introduced some years ago as the result of the studies of Nicolaier. He found that the administration of this agent greatly increased the amount of uric acid in the urine—sometimes as much as 200 or 300 per cent.—without a corresponding increase in the other nitrogenous bodies. This fact has been abundantly confirmed and holds true in both gouty and normal men and for all sorts of diets. The theory which has been advanced that the increase in the output of uric acid was due to an increased formation of this substance in the body is no longer tenable because the observations of Folin and Lyman have shown that there is accompanying the increased output a diminution in the amount of uric acid in the blood. We must concede, therefore, that the drug in some way raises the permeability of the kidney for uric acid. Because of this effect it was argued that it would prove a useful remedy in gout. The chain of reasoning is weak, however, in one link, namely that at present we have no definite knowledge of the relation between gout and uric acid, although the disease seems in some way to be associated with disturbances of purin metabolism. Nevertheless there is a certain amount of clinical testimony of the value of the drug in gouty conditions. Phenylcinchonic acid appears also to possess some analgesic powers apart from its influence upon uric

acid secretion and has been used in other forms of arthritis.

Another substance originally introduced as a proprietary, which has received official recognition, is cotarnine, of which the hydrochloride is official. This alkaloid, which is manufactured from narcotin, has been used under the trade names of stypticin and of styptol. Its most important physiological action is a stimulating influence upon the unstriped muscles, especially of the uterus. By virtue of this effect it is a valuable remedy in various forms of uterine hemorrhage. Just as in the case of ergot, the effect of cotarnine in uterine bleeding has led to its employment in other forms of internal hemorrhages. There is, however, no rational explanation of any styptic action and in the absence of any scientific reason I am constrained to be skeptical of its real value in these conditions, despite a considerable number of clinical reports which are apparently favorable.

Among the drugs of non-proprietary character which have won their way into the Pharmacopœia I might mention sodium cacodylate, calcium and sodium glycerophosphates, emetine hydrochloride, quinine and urea hydrochloride, and trinitrophenol. The cacodylates were so clearly and conclusively presented to this society some years ago by Dr. Dawes that it does not seem necessary to say anything more about them, except to warn against their administration by mouth which frequently gives rise to an almost unendurable garlicky taste and odor.

The question of the effects of the glycerophosphates upon bodily nutrition, especially of the nervous system, is as yet *sub judice*. The experiments bearing on its utilization by the tissues have been so extraordinarily contradictory that it is impossible to draw final conclusions. The mass of evidence, however, seems to me to strongly indicate that they are little, if at all, more easily metabolized than the inorganic phosphates. But even if it were finally determined that the glycerophosphates were of no value from the nutritive standpoint that does not necessarily preclude their therapeutic usefulness. It is pretty well established that elemental phosphorus stimulates the growth of bone, but in view of the infinitesimal doses employed it is absurd to imagine that it supplies the needed element for the synthesis of bony tissue. Its action is much more rationally attributed to some stimulating influence upon anabolism of the same nature as that caused by arsenic or quinine or various other drugs. While not as yet demonstrated it is not unreasonable to consider the possibility that the glycerophosphates may exercise a similar stimulant effect upon the vital chemistry.

Trinitrophenol, more familiarly known as picric acid, has for many years been highly esteemed by a small group of surgeons, especially in the treatment of burns. The recent investigations of Schamberg and Kolmer have established that it is a very much more potent germicide than carbolic acid; they give its phenol coefficient as between 4 and 5. It differs from phenol in being actively astringent as well as germicidal. It is likely to become of increasing importance in certain skin diseases as well as in burns and other open ulcers. It has two disadvantages which militate against its greater popularity, first its powerful staining properties and secondly the occasional occurrence of dermatitis from its use. A most extraordinary dermatitis occurs among the workers in munition factories who come in contact with picric acid.

As there have been nearly forty drugs, not including new preparations, which have received official recognition for the first time it is manifestly impossible to consider them all in detail.

Besides those already considered may be mentioned betaeucaine hydrochloride, creosote carbonate, bismuth betnaphtholate, quinine and urea hydrochloride, emetine hydrochloride, and a number of others. An entirely new departure has been made in the recognition of compressed gases, of which nitrogen monoxide and oxygen have been admitted.

Of the new pharmaceuticals attention may be called in the first place to the powdered extracts, which are for the first time official. The majority of the extracts of the U. S.P. IX are now in the form of powder, although cannabis indica, ergot, hyocyamus, sumbul, gentian, and one or two others less important are still directed to be of pillular consistence. Among the extracts is found the Extractum fellis bovis which replaces the old purified ox-gall. This extract of ox-gall is practically the same as the compound commonly called sodium cholate and is practically a mixture of the glycocholate and taurocholate with small quantities of organic impurities plus the addition of sufficient starch to make one part represent eight parts of ox-gall.

Another interesting type of pharmaceuticals are the magmæ of which two have been admitted, Magma bismuthi, or milk of bismuth, and Magna magnesiæ, or milk of magnesia. These are suspensions respectively of bismuth and magnesium hydroxides without the intervention of any mucilaginous vehicle, and offer a convenient way of administering these drugs. One fluidrachm of the milk of bismuth corresponds approximately to 4½ grains of bismuth subnitrate. Each fluidrachm of the milk of magnesia represents about 3 grains of magnesium oxide.

A novel departure of great interest to the physician is an article in the appendix on diagnostical reagents and clinical tests. This includes formulæ for the preparation of various solutions used in the clinical examination of urine, of blood, gastric contents, and sputum, as well as directions for the preparation of the various culture media and stains frequently used in bacteriology. If you have ever wanted to have a druggist make up a small quantity of Toisson's solution in a hurry or wanted to know the proportion of citric acid in Esbach's reagent, you will not have to be shown the practical utility of this collection of formulæ.

I have trespassed already too much on your patience although I have only touched on some of the more salient features of the Ninth Revision of the United States Pharmacopœia. In conclusion I would say to you, Get a copy and study it and you too will become boosters.

1905 Chestnut Street.

Sloughing Erythema Following Injection of Adrenalin.—Merklen and Lioust have seen four cases of this sequence at the site of injection. The probable mechanism was overaction of the vasoconstrictor property of the drug and suggests that the dosage used may be too high.—*La Presse Médicale.*

RATIONALE, INDICATIONS, AND CONTRAINDICATIONS OF THE NAUHEIM BATH.

By CLARENCE W. LIEB, A.M., M.D.,

WATKINS, N. Y.

THERE seems to be a general misconception among medical men concerning the therapeutic value of the Nauheim bath in diseases of the circulation. This therapeutic procedure is at present suffering from the unmerited neglect which inevitably supervenes when a method is used as a panacea. It has been only within recent years that the method has been critically studied. Yet even with all our refined instrumental methods of investigation and with the vast array of clinical evidence available we find many eminent authorities differing radically in their conception of the rationale and indications of the carbonated brine bath. This divergence of opinion varies from Mackenzie's rather satirical deprecation of the method to the Schott brothers' almost fanatical belief in it. This unfortunate discrepancy is due largely to the following reasons: (1) Lack of standardization of the chemistry and modus operandi of the bath. (2) Misapplication of the method due to divergent conceptions of its rationale, indications, and contraindications. (3) Commercialization of the method with the resulting tendency to prejudice the profession against its use.

With reference to the first reason above mentioned we find that clinical statistics include results obtained with both the natural and artificial Nauheim baths only too often influenced by the prejudices of overenthusiastic observers. Likewise this or that component of the bath is emphasized as the *pièce de résistance* of the therapeutic action according to its predominance in the waters of the Spa whose healing powers are being vaunted.

Then when one considers the frequent slipshod methods of prescribing a course of baths, the variations in the technique of administering the baths, and the different environments in which they are given is it any wonder that the method produces such variable and often disappointing results! Passing to the second reason we are dealing with a method which unfortunately has attached to it the opprobrium of being used as a cardiopathic "cure-all." Since the beginning of the present war the writer has had the opportunity of studying the cases of a large number of Nauheim devotees whose circulatory derangements have run the entire gamut of diagnostic possibilities. All had received a course of Nauheim baths and all with a few exceptions felt that the baths had either cured their particular cardiac difficulty or had checked its progress. The bath records which a large number of these patients carried with them were practically identical. Very little prescription individualizing was noted. We are forced to the conclusion that a large part of the benefit derived from a trip to Nauheim is due to the ocean voyage en route, the hope of a cure engendered by the advising physician at home, and the careful regimen as to diet, rest, exercise, and medication. Undoubtedly these benefits often neutralize in many instances the otherwise baneful effects of the baths which so general a method must necessarily produce. But in spite of all the negative evidence which we can collect deprecating the Nauheim methods no other proof of its value in cardiopathic treatment is needed than to note the success which the method has met during the most progressive and conservative period of medical history. The testimonies of many thousands of grateful patients and the recommendations of scores of eminent heart specialists give us an array of evidence which cannot be easily gainsaid. Hence it is not additional proof as to the value of the method that we need so much as it is a clearer understanding among the profession of the physiological action and therapeutic indications for the carbonated brine bath to which is attributed so large a part of the benefits of the Nauheim method. In this article the writer will attempt to sum up our present knowledge of carbonated brine therapy. The writings of Winternitz, Mueller, Schott, Grödel, and Baruch have been freely consulted and supplemented by the writer's own observations and experiments.

The principal agents entering into the composition of the Nauheim bath are the carbon dioxide gas and the salines, chief of which are calcium chloride and sodium chloride. Most of the natural waters used in giving the baths contain other mineral salts in addition to the above. They also show varying degrees of radioactivity. It is not the purpose of this paper to discuss the relative merits of the natural and artificial Nauheims. Suffice it to quote Schott on this point who says, "Clinically, highly gratifying results may be obtained in cases of heart disease by the use of such (artificial) baths, but their action is decidedly not identical with that of the natural water." It seems to be the opinion of those who have had a large experience with both kinds of baths that the maximum good can be obtained only by the use of the natural waters.

Physiological Action.—Carbon dioxide gas when in solution in water shows a faintly acid reaction and is supposed to contain carbonic acid in solution. In the Nauheim bath it adheres to the surface of the body in small bubbles, thus insulating the skin from the water and protecting the surface of the body from loss of heat. The gas being above the indifferent temperature gives the skin a stimulus of warmth since the indifferent point of carbon dioxide gas is much lower than that of air. This sensation of warmth permits of baths of otherwise prohibitive temperatures to be taken with the advantage thereby of obtaining the maximum of effects of thermal stimuli. Müller states that the action of the carbon dioxide bath upon the circulation has the paradoxical effect of a warm and cold bath given simultaneously. The action of the carbon dioxide upon the skin is to produce a marked hyperemia. According to Baruch this is due to a specific mechanicochemical irritation by the gas and not to a reflex action upon the vasomotor system. This author also has shown that the gas produces a constringing action upon the unstriated muscular structures of the skin.

Filehne and H. Wintermitz have shown that the carbon dioxide gas is absorbed through the skin and thus activates the respiration.

Baruch is of the opinion that the heart muscle is also stimulated by the direct action of the gas upon it. In some unpublished experiments of the writer it has been found that during and after a Nauheim bath the carbon dioxide tension of the

alveolar air has been greatly increased and that this increase varies directly as the concentration of the gas in the water and that which escapes into the air. The amount of gas absorbed through the skin, as shown by this method, is almost negligible as compared to that which is inhaled. This knowledge has been put to a practical application in prescribing the baths in view of the fact that carbon dioxide inhalation increases blood pressure. Patients in whom increase in blood pressure is contraindicated are prevented from inhaling the gas by placing a gas-proof canopy over the bath tub and fastening it about the patient's neck. And conversely in low tension cases, unless otherwise contraindicated, the inhalation of the escaping gas is encouraged by arranging the canopy in such a way as to increase its concentration in the inspired air.

Wieland and Veiel by careful plethysmographic studies have shown that the hyperemia of the skin produced by the carbon dioxide bath is not due to a vasodilatation. The caliber of the capillaries is diminished. The hyperemia is due to an accelerated circulation, the blood being driven with more energy to all parts as a result of increased ventricular action. This positive resistance to the flow of blood in turn results in enhancing cardiac energy since it promotes cardiac effort.

Salts.—We have no evidence to show that the saline elements of the bath are absorbed through the unbroken skin. They act simply by imbibition, penetrating to the peripheral nerve endings of the integument and stimulating them. The salines after drying remain deposited on the skin and produce a powerful rubifacient action. The calcium chloride being hygroscopic keeps the skin moist, thus producing a peripheral hyperemia which tends to give the heart a physiological rest. The Chloride of sodium has been shown to promote the penetration of gas through the skin and its entrance into the blood. The salines assist in retaining the gas in the bath, thus preventing its escape and thereby improving the supersaturation.

Radium.—That radium has a physiological rôle in the Nauheim baths as given at Nauheim, Saratoga Springs, and the Glen Springs is quite certain. The almost fabulous cures frequently reported at many foreign and native spas cannot be accounted for by the mineral content of the waters alone. Their radioactivity, in the light of our present knowledge of its action on the human organism, is undoubtedly an important contributing factor in the curative process. It has been proven experimentally that radium emanation is absorbed through the skin according to the law of gas absorption. Regardless of the method of administration, the physiological effect is the same. It is a powerful metabolic stimulant, probably due to its ability to activate the endocrine glands. It tends to lower blood pressure and has a markedly diuretic action. Its effect upon the blood is to increase the red cells of the body and their hemoglobin content. So potent a physiological agent must obviously be a factor in producing the favorable results attending the use of the Nauheim baths and may account for the superiority of the natural over the artificial baths.

Thermic Effects.—That the temperature of the Nauheim bath determines to a large degree its physiological response is unquestioned. Plain brine baths between 92° and 98° F. produce first a short rise of blood pressure and a slight slowing of pulse rate. Below 92° F. they produce an increase of blood pressure throughout the bath and a decrease in pulse rate. The lower the temperature the more marked is the blood pressure increase and pulse decrease. The thermic excitation of the cold produces a reflex vasomotor effect by stimulating the peripheral nerve endings. The constriction of the superficial vessels promotes cardiac gymnastics, thereby increasing the heart's efficiency.

Temporal and Pressure Effects.—The duration of the bath naturally influences its reaction. This and the frequency of the baths are determined according to the needs of the individual case. The pressure of the water on the body while in the bath should be considered, although its influence is a minor one. The greater the concentration of the brine the greater the pressure on the body, resulting in increased cardiac effort. So evident is this in certain cardiopaths that it is necessary to keep the precordium above the water level to prevent palpitation or dyspnea.

To summarize, it may be said that no one element in the bath is wholly responsible for its physiological reaction. This is due to a sum total of its constituent parts, each being a contributing factor. Failure to recognize this fact accounts for the wide discrepancy in the results obtained by different observers.

Specific Cardiovascular Action.—Heart Muscle: The special properties of the heart muscle influenced by the carbonated brine baths are those of tonicity and contractility. When these functions are below normal the ventricular walls are dilated and weak. As a result the heart's contraction is feeble and in diastole the venous inflow stretches the ventricular chamber abnormally. The carbon dioxide absorbed into the circulation while in the Nauheim bath through the skin and respiratory apparatus increases the heart's tone and contractile power, thus promoting the force of systole and prolonging diastole. Owing to an absence of an excessive amount of venous blood in its cavity the heart becomes reduced in size and the heart by having more room for contraction, contracts more vigorously and takes a longer time, thereby increasing its muscular strength. As with digitalis the action of the Nauheim baths on the normal heart is not very great, hence deductions made from experiments on normal subjects are fallacious.

Systemic Arteries: Plethysmographic studies have shown that contrary to what was formerly believed the Nauheim bath produces a constriction of the peripheral arteries. The hyperemic skin following the bath is due to an increased peripheral blood supply rather than to a dilatation of the vessels. It is possible that the carbon dioxide may act by stimulating the arterial muscle coats and vasoconstrictor center in addition to a primary effect upon the heart. The increased peripheral resistance is in itself a resistance stimulus to the heart. Like digitalis the carbonated bath increases the output of blood from the heart, increases peripheral resistance, and increases the quantity of blood in the arteries at the expense of that in the veins.

An absence of slowing of the pulse during the bath must be taken as evidence of the inefficiency of the bath in producing the desired effect unless the heart's irritability is increased by toxic processes. In functionally efficient hearts a rise in blood pressure is produced with baths given below the neutral zone of temperature.

Coronary Vessels: The increased force of systole produced by the carbonated brine bath by enabling the coronary veins to empty more completely produces a greater supply of arterial blood to the heart, thus promoting its nutrition. The increased pressure in the aorta and ventricle also accelerates the blood supply of the heart through the coronaries, which, together with the prolongation of diastole, produces a more efficient metabolic change in the myocardium.

Kidneys: The factors affecting the flow of blood through the kidneys are the degree of arterial pressure and contraction of the renal arteries and the freedom of the venous outflow. When there is venous back pressure, a contraction of the kidney arterioles or a lowered blood pressure there is a lessening of urinary excretion with its coincident results. The carbonated brine bath by promoting cardiac activity increases the blood flow through the kidneys, resulting in diuresis and the removal of venous stagnation.

Veins: The action of the Nauheim bath upon the venous system is an indirect one. Increased venous pressure (as roughly judged by the height above the angle of Louis at which the veins collapse) due to engorgement of the right heart falls gradually as the number and strength of the baths increase. Varicose veins and hemorrhoids often show very noticeable diminution in size during a course of baths. Though this is affected largely as the result of an accelerated arteriovenous exchange we are led to believe that local nutritional changes in the vessel walls, with increased tonicity, are in part responsible for the frequently observed improvements.

Respiratory System.—During the Nauheim bath the respiration becomes stronger, deeper and slower. This is due to the direct action of the carbon dioxide upon the respiratory center. Respiratory embarrassment in cardiac disease is improved by the baths owing to the removal of pulmonary edema and congestion.

Nervous System.—The carbonated brine baths were originally given for neurological affections. Improvement in these conditions was undoubtedly due largely to circulatroy influences hastening the repair of degenerative processes and functional disturbances. The increased blood supply to the brain quickens mental processes. The vagus and vasoconstrictor nerves are influenced by the baths and accounts for the often observed improvement in vagotonic conditions during and after a course of the carbonated brine baths.

Endocrine System.—Unfortunately we have no clinical methods of measuring glandular activity. We are dependent entirely upon symptoms and signs, thus limiting the conclusiveness of case reports. Judging from the remedial effects of the carbonated brine baths in many cases of myxedema and in climacteric disturbances we are forced to the conclusion that these baths must in some way influence glandular activity. Though this deduction is only empirical, it is nevertheless well worth our serious consideration, even if we cannot scientifically explain it. The radioactivity of the water may in part or wholly account for the effect. On the other hand, the improved circulation induced by the bath may affect the secretory activity of the gland, or again this may be influenced by a specific action of the carbon dioxide on the glandular elements. In exophthalmic goiter the benefits derived may be primarily circulatory, or in the light of some recent observations may be the result of nerve blocking. We must admit that we are still groping in the dark when it comes to a rational understanding of the interrelation of the endocrine glands and the processes which occasion their hypo- or hyperactivity.

The rational prescribing of a course of carbonated brine baths presupposes a careful diagnosis of the condition to be treated. This is as important, if not more, than when contemplating digitalis medication, because the treatment is more drastic and involves specific gymnastic exercise in which the heart bears the brunt of the burden. While an anatomical diagnosis is very important the information thus obtained is not the final word in deciding the question of Nauheim treatment. A functional estimation of the cardiovascular apparatus gives us a more accurate valuation of the heart's efficiency, and therefore of the heart's response to the baths. It enables us to weed out cases to which the baths are either unnecessary or unsuited. For example, hearts with valvular lesions which are well compensated subjectively and objectively are neither materially benefited by a course of baths nor injured. On the other hand, functional diagnosis helps us to reject cases which are not able to tolerate the baths and thereby offsetting possible untoward effects and preventing disappointment to both patient and physician. Information is obtained which often indicates that with continued digitalis medication and rest the baths may be resorted to, subsequently, with safety when the heart has developed some reserve strength. Any of the functional tests may be advantageously used in which the response of the blood pressure, pulse rate, and subjective sensations to exercise are studied. The writer finds that a patient's response to a test Nauheim bath often settles the question in the more doubtful cases. Such a test bath should be at the neutral zone of temperature, *i.e.* 92°, and mildly carbonated and given for a period of at least five minutes. Obviously, even though a patient's condition does not warrant such fine distinctions his response to the increasing strength of baths should be watched and the strength never increased without a renewed estimation of his circulatory efficiency.

In considering (*infra*) the application of the carbonated brine baths to the various specific circulatory disturbances the writer merely attempts to record the gleanings of his experience in giving the baths to a large number of cases. It is not possible to give clear cut indications and contraindications in diagnostic terms for the carbonated brine bath regimen, since, as above emphasized, a functional diagnosis is the only logical and scientific way to determine this.

Arteriosclerosis.—The majority of patients taking the Nauheim treatment have passed the meridian of life. A big percentage of these show marked degenerative changes of the cardiovascular system. The arteriosclerotic group, frightened by the dramatic articles in the lay press and the tragic statements of the medical alarmist regarding the imminent peril in which their condition places them, rush to the geriatrist and down the line of "ists" for relief from their malady. The hydrotherapeutist gets more than his share and too often prescribes for his patient without being cognizant of the limitations of his armamentarium. The Nauheim treatment has erroneously been considered among most patients and many physicians as a specific for arteriosclerosis, but in point of fact the Nauheim bath has a very limited application in this condition. It should be remembered that the younger the subject and the less impaired at any age are the cordiovascular tissues, the more certain will be the normal physiological response to the Nauheim bath. A high blood pressure with marked evidence of arteriosclerosis is a definite contraindication to the treatment. We should not overlook the fact that high blood pressure is not synonymous with arterial hardening and vice versa. We often observe cases with normal blood pressure readings who show generalized sclerosis; obviously such cases should, if given the Nauheim baths at all, be watched with fear and trepidation. Cases showing a high diastolic pressure contraindicate the treatment.

The writer wishes to emphasize the evidence given by a careful ophthalmoscopic examination as one of the best guides to hydriatic treatment. Fine tortuous vessels seen near the macula or near the disk, tortuous retinal arteries and veins showing white streaks along their sides, veins which are indented or dilated beyond the point where an artery crosses, arteries showing white and red patches over their course, hemorrhages and exudates on the retina augur strongly against the expediency of a course of carbonated brine baths. If, however, the above abnormalities are slight in degree and no other clinical contraindication is present the baths may at least be given a trial. When the eye grounds show marked tortuosity, thickening, etc. (ruling out congenital lesions), even though there are no other objective signs of arterial degeneration, the Nauheim baths are contraindicated. Cases giving a history of recent cerebral irritation (vascular spasm) or apoplexy, emaciated patients with tortuous and sclerotic systemic arteries should not risk the baths. The physician should be on the lookout for evidence of local arterial degenerations when contemplating Nauheim therapy. The expedient of making arterial readings on both arms, as pointed out by Hoover, helps us in this direction. The evidence given by functional tests contrary to the general rule as a guide to hydriatic treatment is of less value in arteriosclerosis than is a careful anatomical diagnosis.

The writer has found that baths above 98° F. and below 92° F. by increasing cardiac load are not indicated in even the milder cases of arterial degeneration. Patients do better in baths between 96° and 92° F. from 5 to 20 minutes' duration and noncarbonated. The effect of even such mild baths on the patient should be carefully watched. Patients in whom the peripheral circulation is not enhanced, as evidenced by failure to show a reddened skin reaction after the bath, and particularly after a brisk rub, are usually poor subjects for the bath.

Hypertonia.—Treatment aimed at reducing a high blood pressure should not be attempted without first determining the pathology of the hypertension. This is essential, no matter what line of treatment we are instituting, whether medical or physiotherapeutic. The latter treatment is usually the more intensive, hence the chance for untoward effects are correspondingly greater. This should occasion special diligence in ascertaining the causative factor present in a given case. For convenience we may classify high blood pressure as follows:

1. Cardiac Failure High Blood Pressure: In this condition the carbonated brine bath should never be given until the pressure has first been lowered by rest, bleeding, catharsis, or sweating. The baths are then given primarily to increase cardiac efficiency, for by so doing the pressure is kept down, promoting elimination and improving the capillary return.

2. Nephritic High Blood Pressure: This type of hypertension, when uncomplicated, at least, warrants a trial with the carbonated brine baths, but in no case should the baths be given below the neutral zone of temperature; these cases often do best in plain brine baths without the carbonization.

3. Essential High Blood Pressure: This heading comprises the cases which have no urinary evidence of nephritis. These cases usually show good response to the Nauheim treatment.

4. Symptomatic High Blood Pressure: By this is meant that in aortic insufficiency, lues, diabetes, asthma, and hyperthyroidism. Only in the latter two conditions are we justified in holding out a promise of lowering the tension. However, by promoting the general metabolism the bath can be advantageously used as an adjunct to the orthodox treatment of lues or diabetes. Relative insufficiency due to the relaxed aortic ring is usually benefited, the improved tonicity of the heart muscle resulting in a narrowing of the aortic orifice. When the dilatation is due to an aneurysm or marked atheroma just above the aortic ring the baths are contraindicated.

5. Neurogenic High Blood Pressure, such as that accompanying nervous strain, the climacterium, or due to persistent insomnia, is as a rule greatly reduced by a course of carbonated brine baths. In point of fact there is no better method of treatment for the symptoms attendant upon the menopause than a judicious course of Nauheim baths. The effect of the baths is often very striking. It is possible that the rationale of the cure is due to the stimulation of the hormonopoietic system.

Obviously when a high blood pressure is the result of compensatory influences it should not be reduced unless it is so high that arterial rupture is threatened. In our experience a blood pressure above two hundred is presumptive evidence that the carbonated brine baths are contraindicated. When treating high blood pressure by means of the Nauheim regimen we should attack the problem from all sides, using every possible weapon we have.

Better results are often obtained in reducing a high blood pressure when autocondensation electricity is used in conjunction with the baths. Just what the physiology of this is the writer is not able to say, although the influence is unmistakable.

Hypotonia.—Low tension cases are the ones which usually make the best response to the treatment herein discussed. This is true whether the low pressure is due to a weak heart muscle or to a systemic vasodilatation. The latter condition, according to Romberg and Passler, is the cause of hypotonia following the acute infections. The heart in these postinfectious cases practically always shows evidence of a weakened myocardium. The Nauheim baths therefore have a dual influence in these conditions, namely, by their vasoconstrictor action on atonic blood vessels and by their specific effect upon the heart muscle itself. Their indication, consequently, in the residual circulatory weaknesses attendant upon such diseases as typhoid, diphtheria, polyneuritis, influenzā, etc., is apparent. The low tension of adrenal insufficiency is often favorably influenced by the baths, both by their vascular stimulation and through their action on the gland itself. The hypotension of splanchnic neurasthenia, vagotonia, and conditions showing more than a local relaxation of the walls of the veins is often benefited. Venous atonia suggests a condition which might be termed a chronic low grade acapnia, in which the carbon dioxide, or "vasomotor hormone," as it is termed by Henderson, is deficient. The Nauheim bath furnishes a method by which the gas is absorbed through the skin and lungs, thereby stimulating the vasomotor center and restoring the normal physiological balance.

Myocardial Insufficiency.—As regards the treatment of this condition by means of the carbonated brine baths, a division of the subject into three groups of cases is in order: (1) Cases showing symptoms of incipient decompensation as evidenced by slight dyspnea on exertion, easily induced fatigue, and objectively by a slightly tender liver and a few basal râles. (2) Moderately advanced cases showing considerable dyspnea, cardiac dilatation, enlarged and tender liver, pendent edema, and a diminished urinary output. (3) Severe cases with life in jeopardy who are orthopneic and have developed anasarca and serous effusions, marked cardiac dilatation, static albuminuria, and oliguria.

It should be set down as a hydriatic law that the carbonated brine baths should never be given to cases in which the heart does not possess a degree of reserve power sufficient to meet the increased demands placed upon it by the bath. Carefully conducted and repeated functional tests, noting pulse, blood pressure, and subjective reactions before and after the tests will give the requisite information as to the myocardial reserve. Distention of the right heart, let it be remembered, dictates special precautions with regard to measures which accelerate the return of venous blood.

Regarding the first type of case above mentioned, we know that when dyspnea and hepatic tenderness have ensued decompensation is threatening. When this condition has developed slowly and there are no other untoward signs threatening it invites the application of the Nauheim bath and gives promise of good results. Even in those early cases we should proceed with extreme caution. The patient should be kept in bed during the half day in which the bath is taken (preferably in the morning) until the dyspnea has disappeared. Then he may advantageously be given the Schott resistance exercises and later allowed to take the gradually increased grades of the Oertel terrain paths. The fact must not be overlooked, when increasing a patient's cardiac load, that increased breathlessness spells decreasing circulatory efficiency. The degree of breathlessness may be taken as an index of the amount of cardiac subefficiency.

It is interesting and instructive to note the number of patients returning, yearly or biyearly, for a Nauheim cure with signs of threatening decompensation who, during their course of cardiac efficiency upbuilding, acquire enough myocardial reserve to meet the exigencies of their environment for several months and stave off the incidence of cardiac collapse.

The second type of case noted above is the one which more often than any other goes to pieces on its hydriatic Charybdis. These are the cases frequently referred to Spas for treatment in the anxiety to effect a speedy check or cure of an obviously progressive condition. These are the cases which by all means should be spared the strain of travel and should receive the orthodox medical care preparatory to the Nauheim routine. Should institutional treatment seem indicated it should be impressed upon the patient by his physician that before having recourse to the Nauheim routine he must undergo a preparatory treatment. The patient, accordingly, should be kept in bed on a strict diet with full doses of digitalis or the precordial coil (called by Baruch our hydritic digitalis) may be used and the emunctories kept freely open. Not until a week after the signs of decompensation have disappeared should the Nauheim baths be instituted, and only then with such careful adaptation and modification as may be indicated in that particular case.

The third type of case, or those with signs of absolute decompensation, emphatically contraindicate the treatment under consideration.*

It should be remembered that recovery from an advanced state of myocardial insufficiency is only to be expected when the heart muscle still has a fair amount of residual strength, such as is noted within the first five decades of life in patients recovering from infections, toxic myocardias, in those with valvular lesions and those in which signs of insufficiency have set in as the result of excessive physical strain. If the insufficiency is due to senile changes accompanying advanced arteriosclerosis or is a terminal stage of a contracted kidney but very little can be done, no matter what kind of treatment is given. In relative insufficiency of the heart muscle treated by means of the Nauheim baths murmurs often disappear, and that as a consequence of a stronger and slower heart action the weak heart sounds often become louder and tachycardia and arrhythmia often disappear.

*To subject patients of this type to the ordeal of Nauheim bath therapy is committing an unpardonable therapeutic crime!

Valvular Lesions.—The adaptability of cases to the Nauheim treatment will depend, as above indicated, upon the responsive power of the myocardium rather than on the nature of the valvular lesion. This latter condition even at the present time is emphasized out of all proportion to its importance even to point of minimizing the more common and serious types of heart affections unassociated with valvular defects. The degree of the valvular inefficiency is unimportant if the cardiac muscle has escaped degenerative changes. However, if the muscle is damaged a slight valvular defect may be enough to precipitate cardiac failure.

Romberg has shown that in normal hearts in which valve lesions have been experimentally produced the reserve power has been but slightly modified. Before considering the applicability of the carbonated brine baths in valvular lesions it should be borne in mind that where compensation is good in a heart with no other defect than that of a valvular lesion any attempt to increase the reserve power of that heart by measures aiming at a greater cardiac hypertrophy is unjustified.

Mitral Insufficiency: Experience has demonstrated that in relative or muscular insufficiency of the mitral ring and with the condition otherwise uncomplicated excellent results may be expected by the use of the carbonated brine baths. There is nothing to be gained in giving a course of Nauheim baths to a patient with mitral insufficiency due to valvulitis with a heart which is otherwise normal.

Aortic Insufficiency: In general the Nauheim baths are not conducive to improving hearts with this type of valvular defect. Here, of course, we must be guided by the condition of the heart muscle. Those cases due to luetic aortitis, to arteriosclerosis, or to endocarditis lesions are obviously not improved by the treatment. The Nauheim bath, by prolonging diastole, tends to further distend the left ventricle, thus increasing its hypertrophy or dilatation. Relative aortic insufficiency due to a relaxed aortic ring is worth a trial with the Nauheim baths when other methods fail. They, however, should be given with the greatest watchfulness.

Mitral Stenosis: Slightly decompensated hearts with a mild degree of mitral narrowing respond very satisfactorily to the Nauheim baths. However, when the condition has progressed to the point where the left ventricle becomes atrophied and merely an appendage, as it were, of the hypertrophied right ventricle, the baths are not only valueless, but may do positive harm. Patients with a small left ventricle are usually poorly developed and badly nourished. When they are given the baths the peripheral circulation being poor and slow to respond to stimulation, there is a chilling of the body, with the resulting depression instead of stimulation of the circulation.

Aortic Stenosis: The carbonated brine baths are, as a rule, inappropriate in cases of aortic stenosis. This condition being usually met with at a more advanced period of life than aortic insufficiency is generally associated with extensive calcareous changes in the arterial system, which by continuity frequently involves the coronary arteries. Systole is already prolonged, often as much as twenty-five per cent., and the ventricle greatly hypertrophied. The peripheral resistance produced by the bath, added to the impeded blood flow due to the stenosis, puts too great a strain on the myocardium and may lead to dilatation. The writer has never seen a frank case of aortic stenosis benefited by a course of baths.

Cardiac Hypertrophy.—The process of hypertrophy, from whatever cause, consists, histologically, of an enlargement of the individual muscle fibers. The absolute power of the heart is not increased, the heart simply being enabled to use its remaining power to better advantage. The degree of hypertrophy is an essential factor in determining the indications for the Nauheim baths. Obviously, if the heart has hypertrophied to its limit any treatment based upon the principle of cardiac hypertrophy is illogical. The Nauheim baths are valueless in well compensated hearts, a fact not to be forgotten. Hearts in which the hypertrophy is due to stenotic factors and showing signs of collapse do not do so well on the Nauheim therapy as those in which the hypertrophy is due to an increase in the amount of blood conveyed to the heart during diastole necessitating an increased volume of blood to be moved at the next systole.

Angina Pectoris.—Any consideration of the physiological treatment of this condition must naturally concern itself with the underlying morbid anatomy. In cases of true angina associated with sclerosis of the coronary arteries or the aorta, the principles of treatment enunciated under the caption arteriosclerosis are applicable. The baths should never be given when the signs and symptoms of the disease are marked. Unfortunately, however, these are just the cases which are prone to resort to drastic treatment without proper medical advice, resulting only too often in irreparable harm or fatal consequences. In questionable cases the baths should never be given below the neutral zone of temperature. If anginal symptoms, no matter how mild, are produced by the bath, this form of treatment should be discontinued. Some authors hold that the Nauheim baths are contraindicated if the paroxysm of pain is not relieved by nitroglycerin. In the milder cases of true angina the baths often do an immense amount of good. Their antispastic action on mildly sclerotic coronaries, by relieving the resulting ischemia, improves cardiac nutrition. The vasomotor anginas associated with the abuse of tobacco, tea, coffee, and in highly neurotic individuals respond very satisfactorily to carbonated brine baths. Too many cases, however, with precordial pain are regarded as vasomotor in origin and risks taken which should be avoided.

The Heart in Obesity.—Obese individuals may have hearts which apparently functionate normally. In other words, obesity *per se* does not necessarily produce cardiac inefficiency. The attendant inactivity produced by corpulency tends, however, toward the development of myocardial weakness more quickly than the same amount of inactivity in individuals of normal weight. This is due to the disproportion between the size of the heart and body weight, fatty infiltration of the heart muscle, and pericardial incumbrance of fat. In the treatment of the insufficient heart of obesity with the Nauheim baths we should, naturally, be guided by the degree of decompensation. In Spa treatment,

owing to the limited time which we have for treating these patients, treatment must often be directed toward both the obesity and heart simultaneously. The most logical procedure is, of course, to direct one's attention to the heart's deficiency before attempting reduction, but experience has amply shown that these patients can be safely reduced providing the circulatory mechanism is reinforced by the carbonated brine baths. As a consequence these baths may be prescribed routinely in treating obesity providing the heart's reserve is sufficient to stand the increased work placed upon it by the baths. We know from autopsy evidence that in reducing body weight the fat about the heart is the last to be diminished by the treatment. The Nauheim bath in these cases whips up the sluggish, obese heart, and thus assists in reducing the pericardial and myocardial fat, at the same time increasing the heart's tonicity. If in the treatment of general obesity the heart is guarded by the Nauheim baths the reduction treatment can be made more intensive and the chance of finishing an obesity cure with cardiac impairment is reduced to the minimum.

Heart Block.—In this condition due to a disturbance of conduction in the bundle of His, the Nauheim baths, as a rule, are contraindicated. One case observed by the writer showed an unmistakable increase in objective signs and subjective symptoms while taking the baths, even though atropine was given simultaneously. Cases in which the myocardial element is conspicuously associated with faulty conductivity may be given the baths with some assurance of accruing benefit.

The writer has had under his care for a month each year during the past three years a patient, 60 years of age, leading an active life as superintendent of a factory, who has a 2 to 1 heart block with a pulse of 40. On each occasion this patient has come under treatment with definite signs of early decompensation and has taken 18 to 20 baths. The baths had no appreciable effect on his pulse, excepting a lowered rate while in the bath. There was noted on all three occasions, however, a very evident disappearance of subjective symptoms of cardiac overload. The patient reports that for several months subsequent to his Spa treatment there has been a marked improvement in his circulatory efficiency as attested by his repeated return.

Tachycardia.—The rapid heart which is frequently associated with the menopause is generally decreased in rate by the baths. This is only one phase of the improvement of climacteric symptoms noted as the result of the Nauheim baths. Just what the physiology of this reaction, whether endocrine or purely circulatory in origin, it is difficult to say. In the tachycardias which are, in so far as can be determined, purely neurotic in origin, much benefit is derived from carbonated brine therapy. It is quite generally agreed that the Nauheim baths are particularly indicated in cardiac neurosis. With respect to paroxysmal tachycardia the Nauheim baths may be advantageously given between attacks, but in no case should they be given during an attack for fear of increasing the already existing dilatation. In the four cases with this affection treated by the writer there was noted, subsequently, in two of the cases a longer period between attacks and a diminution in their intensity and duration. Obviously, when the condition is associated with marked arterial degeneration the Nauheim baths should not be given.

Hyperthyroidism.—Owing to the frequent remissions and self-limited nature of Graves' disease it is very easy to fall into the error of giving undue credit to the rôle played by the Nauheim treatment if this happened to be the last therapeutic weapon used. In the writer's limited experience in treating these cases with Nauheim baths conflicting successes and failures have attended their use. The hydriatic treatment of the condition is that of myocardial insufficiency and the stage of decompensation determines the indications for the baths. In cases with marked thyroidosis with a fibrillating and dilated heart no hydriatic treatment other than the use of the precordial coil should be instituted. Where the heart symptoms are in abeyance and there is sufficient reserve strength to bear the increased load produced by the carbonated baths these may be used cautiously and with good hope of success. Especially so when nervousness is the presenting symptom and the heart's rate is not above 120. The baths have a very sedative effect subjectively and as a result a rapid, turbulent, or intermitting heart may show a striking improvement. These patients often fall asleep after the bath and the quieting effect of the bath may last for several hours. One patient with drenching sweats as part of the symptom-complex of her condition after but a few baths showed a complete amelioration of this annoying symptom. It is difficult to understand just how the Nauheim baths act in this condition. Besides their circulatory effect they undoubtedly have some influence upon the autonomic nervous system or endocrine glands. Their beneficial effect when given for the glandular unbalance of the climacterium may be accounted for in the same way.

As previously emphasized in this paper, an estimation of the heart's functional capacity should be a prerequisite to a determination of the heart's fitness for the Nauheim baths. When we consider the contraindications for the treatment, however, anatomical morbidity is largely the determining factor. When after a comprehensive clinical and pathological survey of a patient, objections to the baths have been ruled out, we may proceed with the treatment with greater assurance of success. While it is impossible to make a cut and dried list of contraindications to the Nauheim baths, yet the writer's experience has amply demonstrated, to him at least, that the following conditions are inapplicable to the method: cardiac insufficiency with marked edema, dyspnea, or Cheyne-Stokes breathing; tenderness of the liver or effusion into the serous cavities; cases in which cardiac failure is progressing with great rapidity; severe cases of angina pectoris; all extended degenerations of the heart muscle and arterial system; blood pressure over 200 with high diastolic; aneurysm; recent cerebral hemorrhage; aortitis; all but the milder cases of aortic stenosis and insufficiency; the advanced stage of mitral stenosis; all inflammatory diseases of the heart associated with fever, such as myocarditis, endocarditis, and pericarditis. If in this latter condition adhesions have

formed, no good can come from the treatment except by combating the functional disturbance present. If fresh endocardial changes are present the Nauheim baths should not be given. Of especial danger in old valvular lesions is the frequency of recurrent attacks of endocarditis following the acute infections. Care should be taken that the baths are not given at such a time. Congenital and well compensated valvular lesions, though not contraindicating the baths, are not benefited by them.

The success of the carbonated brine bath in the treatment of circulatory affections varies in the hands of different practitioners like that of any other therapeutic procedure. Its scope of application is bounded by sharp limitations, which, if ignored, lead to disappointing and even disastrous results. Administered rationally as to duration, strength, and individualization it ranks as one of our most efficient cardiac upbuilders. In some cases it may be used as the sheet anchor of treatment, in others simply as an adjunct. The method does not preclude the simultaneous use of drug therapy. In fact, the error is too often made of discontinuing digitalis medication directly the carbonated brine therapy is instituted. Not until the effect of the baths has been determined should digitalis be withdrawn, and then only gradually. In consequence of inattention to such details and the frequent haphazard methods of application the carbonated brine cardiotherapy is suffering from cold medical indifference. This is entirely unwarranted, as evidenced by the success with which the method has been attended when scientifically applied.

THE GLEN SPRINGS.

PRESENILE GANGRENE.

THROMBOANGIITIS OBLITERANS—FURTHER CONFIRMATION OF ITS RELATION TO TYPHUS FEVER.

BY CHARLES GOODMAN, M.D., F.A.C.S.,

NEW YORK.

CLINICAL PROFESSOR OF SURGERY, NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; VISITING SURGEON, BETH ISRAEL HOSPITAL AND MONTEFIORE HOSPITAL.

As a conclusion drawn from a personal study of thromboangiitis during the past twenty years, I may say that I doubt the existence of any method which might result in a permanent cure of the disease.

Before gangrene has set in, the various palliative measures such as hypodermoclysis of Ringer's solution, recommended by Koge, the incandescent lamp heat-radiations, the high frequency current, baking, and diathermia may afford a temporary alleviation of the symptoms. If they should fail to give relief to the torturing pain, I believe that a surgical procedure such as the ligation of the femoral vein, as described by Oppel, or an arteriovenous anastomosis between the femoral artery and vein, is indicated. Confronted by a case of thromboangiitis with the presence of gangrene, I recommend to the patient a high amputation as best adapted to put an end to the excruciating pain.

At a meeting of the New York County Medical Society in March, 1916, I presented a preliminary report of a serological study of the possible etiological relationship of typhus fever to presenile gangrene.

While reviewing the literature of typhus fever I noted the fact that presenile gangrene of the extremities is found in almost every country, but is more prevalent in those countries where typhus fever is endemic, as in Russia, Austria, Japan, Turkey, and Bulgaria. This would disprove the common misconception that the condition is one peculiar to the Jewish race —a misconception clearly due to the circumstance that the majority of the cases seen in this city have been poor Jewish immigrants from Russia and Galicia and other countries where typhus is endemic.

Nicotine and alcohol may be dismissed as causative factors; syphilis can be excluded, as Buerger and Kaliski agree with the reports of my cases that the Wassermann reaction has been almost invariably negative. That the disease is a result of disturbances of metabolism is unlikely, as may be seen from the studies in the laboratory of Physiological Chemistry of the Beth Israel Hospital by M. Kahn. As early as the seventeenth century, Jordanus enumerates among the cardinal symptoms of typhus, gangrene of the extremities. Cassirer collects the cases in which symmetrical gangrene was described after typhus exanthematicus by Estländer and Fischer. Jochman comments on the frequency of spontaneous gangrene of the extremities observed in typhus, and attributes this frequency to "an inflammation of the intima of the arteries and subsequent thrombosis which are probably caused by the pathogenic factor of typhus."

Saltikow, Buerger, and others have suggested that thromboangiitis might be caused by some microorganism. Buerger, in a stuly of 50 amputated legs of thromboangiitis patients, observed histological changes in the vessels resembling miliary giant-cell foci which aroused the suspicion of some microbial process. Buerger then looked carefully for spirochetæ, tubercle bacilli, and the ordinary pyogenic agents in cultures and microscopic sections and by the inoculation method, but without result.

In reference to the conclusions of a somewhat tentative nature which I drew from the serological tests with the Plotz bacillus a year ago, the reports of the Bulgarian campaign preceding the European war have confirmed my contention that thromboangiitis is of infectious origin.

Professor Zinsser of Columbia told me in a personal interview that he saw a number of cases of gangrene of the extremities during his recent visit to Serbia.

Emil Wiener, after performing a number of post mortems on typhus subjects, states that the most characteristic pathological evidence of typhus is the extreme fragility of the vessel walls. This may entail thrombotic formation in the vessels of the lower extremities and elsewhere. Eugen Fraenkel concludes that the areas of necrosis shown in the walls of the arteries after typhus must be considered pathognomonic of the disease. That these arterial changes can be seen only with extremely delicate coloring and fixation methods accounts, in Fraenkel's opinion, for the fact that so frequently typhus exanthematicus has escaped observation in post mortem reports.

Dr. George Cheever Shattuck of Boston sent me on December 25, 1916, an abstract of an article he

is writing on the Serbian typhus epidemic in which he states: "Gangrene of the feet seems to have been very common during the cold months in the early part of the epidemic. Dr. Strong said that he saw many cases of it and that in some of them the nose and ears were affected. Maitland made some interesting observations on it. He says that before it appeared, the hands and feet were blue and cold and the pulse thready, that red patches of hyperemia then appeared on the feet, and that gangrene developed in the areas which had been thus congested. Starting from the fact that a frost-bitten part remains for some time afterward sensitive to exposure he presumes that frostbite or exposure in the trenches may have played a predisposing part by injuring the vessels.

"That this form of gangrene is not embolic is evidenced by its frequent symmetry. Moore says that it is probably brought about by artificial thrombosis and it seems likely that Maitland is right in supposing that exposure may be a contributing factor.

"Gangrene heals very slowly, and seems to appear most often in the later stages of typhus or during convalescence. Consequently there were many cases of it in the wards when we began work and others were brought in showing no typhus rash."

Professor Bruno Wolff wrote in September, 1916, that gangrene of the extremities was among the frequent clinical manifestations of typhus, and quotes Professor Brauer of Hamburg as ascribing this gangrene to the specific inflammation of the arterial intima. Wolff cites the report of E. R. Granz, the chief surgeon of the prisoners' camp at Gross Magendorf and that of Schürer von Waldheim as testimonies given lately to the frequent occurrence of gangrene after typhus, and concludes with Fraenkel, Brauer, and Jochman, that the secondary gangrene was due to a vascular lesion produced by the typhus infection. Of these cases Professor E. Schwalbe made histological studies of the post-mortem material and reported that the vascular alterations found in the cutaneous connective tissue corresponded in part to those described by Fraenkel, and in other cases they differed somewhat. Wolff gives beautiful illustrations of cases of gangrene which are identical with those we see here in the cases of thromboangiitis.

It seems more than ever reasonable in the light of the foregoing reports to conclude that the typhus virus has a predilection for the blood vessels, especially of the extremities, that its activity is followed by an inflammation of the intima with the formation of the thrombi with frequent subsequent gangrene of the foot or leg.

I am firmly of the conviction that further studies I have undertaken will bring additional proof to my argument that thromboangiitis is a later manifestation of a previous typhus infection.

THE BALANCED DIET ANALYZED.

By R. H. ROSE, M.D.,

NEW YORK.

It is important for physicians to fix in mind what constitutes a balanced diet. Therefore the writer presents the accompanying sample diet together with a discussion of its salient features. The present war has served to emphasize the economic phase of scientific dietetics. Other phases, relating to health and efficiency, are of high importance at all times. The following points will be discussed: (1) A classification of foods facilitating computation of proteins, fats, and carbohydrates. (2) The amount of protein and meat required daily. (3) Why a large luncheon and dinner usually furnish an excessive amount of protein. (4) Fat and carbohydrate requirements are easily exceeded. (5) How to increase or decrease the caloric content of one's dietary for weight control or for varying degrees of activity.

Food Classification.—The basic feature of the writer's classification of foods is its utility. Articles which might be placed in more than one group are assigned to that one which experience has shown to be the more useful.

Foods are classified as follows:

Proteins: Meats (including chicken and fish), eggs, milk, and cheese.

Fats: Butter, cream, olive oil, and bacon.

The carbohydrates are divided into two groups.

High-Content Carbohydrates	Per Cent of Sugar and Starch	Low-Content Carbohydrates	Per Cent of Sugar and Starch
Sugar	100	Bananas	22
Honey	80	Apples	14
Cereals (dry)	80	Pears	14
Dried figs, dates, and raisins	76	Peas	14
Crackers	71	Lima beans	14
Jelly	70	Parsoips	13
Sponge cake	65	Oranges	11
Bread (all kinds)	50	Squash	10
Apple sauce	34	Peaches	10
Puddings	29	Gooseberries	10
Ice cream	27	Carrots	8
Almonds	25	Beets	7.4
Custard	22	Strawberries	7
Potato	21	Cabbage	5
Corn (canned)	18	Caulitlower	5
Cereals (moist)	17	Onions	5
Macaroni	16	Celery	3.3
Soup (thickened)	10	Lettuce	3
		Spinach	2.6
		Asparagus	2.2
		String beans	1.9
		Clear soops	1.1

Some articles in the second group of the above classification have a higher percentage of carbohydrates than a few in the first. They are so placed because the helpings served do not average as many calories as those of the first group. For instance,

thickened soup, which has been placed in the first group, contains only 10 per cent. carbohydrates, while banana, of the second group, contains 22 per cent. But this grouping is practical because a helping of thickened soup is 160 calories or more, while a banana, when eaten without sugar and cream, is 100 calories.

Minerals are contained principally in fruits, vegetables and the outer coating of cereals.

Amount of Protein and Meat Required Daily.—Protein is the tissue-building element in food, constituting the major portion of muscle and of the body's general framework. Professor Chittenden proved experimentally that man can live in health on 1 3 of a gram of protein for each pound of body weight. The Voit standard, which for many years was considered correct, is a little more than 2/3 of a gram for each pound. To be conservative, while allowing time for ascertaining any possible ultimate ill effect from a standard as low as that of Chittenden, I will place the requisite amount at ½ gram. From our present evidence, the chief danger of the low protein standard lies in the possibility of the diet chosen being wanting in some essential amino-acid. (The amino-acids are smaller divisions of the proteins.)

The ½ gram per pound standard, *i. e.* 75 grams for the average man, is perfectly safe if a fair variety of food is taken. Many persons in every country are not ingesting more than this amount. An individual who is taking a moderate amount of meat once daily seldom exceeds this quantity of protein.

The above diet will serve to show averages in the various food elements. It shows the amount of protein food derived from the articles here classed as proteins and, separately, from articles not here classed as proteins; 47.5 grams are derived from the former and 36 grams from the latter. The average diet, which might be arranged to contain approximately 75 grams of protein, would furnish from 25 to 35 grams from foods not here classed as proteins.

Protein Content of Protein Foods.—100 grams of meat (0.2 lb.) = 23 grams of protein. (100 grams of beef = 5 x 3 x 0.5 inches.) 2 eggs = 13 grams of protein. American cheese (3 x 1 x 1 inches) = 12 grams of protein. Milk (2 glasses) = 17.5 grams of protein. The approximate amount of protein can be obtained by adding thirty grams to the amount chosen from the above list of protein foods. The accompanying diet draws from the protein class 2 eggs, or 13 grams, and a piece of meat 5 x 3 x 0.75 inches, or 34.5 grams. Adding 36 grams drawn from the non-protein articles, we obtain 83.5 grams of protein for the day. Hence it is seen that a good helping of meat once a day furnishes a sufficient amount of protein, although the only other article drawn from the protein class is 2 eggs.

It is apparent that adding cheese and milk or taking a larger amount of meat exceeds the daily protein requirements. Again, it is evident that those who do not take milk or cheese, or much meat, keep within 75 or 80 grams of protein daily.

Why a Large Luncheon and Dinner Usually Furnish an Excessive Amount of Protein.—The average luncheon includes eggs or meat, sometimes both, sometimes more than one variety of meat. The average large dinner includes two or more varieties of meat. This necessarily furnishes an excessive amount of protein, from 150 to 200 grams, exceeding even the Voit standard. Such a dietary necessitates excessive work on the part of the kidneys, liver, and heart. Even a moderately excessive protein ingestion favors protein fermentation with the development of poisonous protein by-products eventuating in the weakening of the three organs mentioned. This moderate excess, if continued over a long period of time, will have a deleterious effect which, though not so apparent, is none the less certain.

Fat and Carbohydrate Requirements are Easily Exceeded.—Fats: Three balls of butter (one ounce) = 240 calories. Six tablespoons of cream (medium grade) = 180 calories. In our sample diet, 440 calories are drawn from fats not here classed as such. Most of this comes from the meat. This totals 848 calories, supplying ⅜ of the day's requirements for one who is living a sedentary life, and is all that

he should take. He will exceed his requirements by taking breakfast bacon, two balls of butter at a meal, and a large amount of cream. On the other hand, if activity is great, or increase of weight desirable, the latter amount of fats should be taken.

Carbohydrates: In the accompanying diet table 1007 calories are derived from the carbohydrates, of which 725 come from the high-content carbohydrates and 282 calories from the low-content carbohydrates. To increase the diet for one of great activity the high-content carbohydrate group may be increased by 50 to 100 per cent. Reference to the diet will show that this refers to sugar, cereals, bread stuffs, macaroni, and potatoes. Other similar articles which may be used are pancakes, mush, honey, jam, muffins, cake, and starchy desserts. It is well to remember that many desserts are rich in fats as well as in carbohydrates.

By referring to the maintenance diet here given, it will be seen that 5 teaspoons of sugar are used daily; that two other articles of high-content carbohydrates, cereal and bread, are taken for breakfast; two for luncheon, bread and macaroni; and three for dinner, thickened soup, bread, and potatoes. A dinner with five or six high-content carbohydrates, as thickened soup, bread, sweet and Irish potatoes, macaroni, and a starchy dessert is too rich in carbohydrates. To reduce the number of calories obtained from carbohydrates as given in this maintenance diet, the amount of bread may be reduced, macaroni withdrawn from luncheon, and the thickened soup from dinner.

We know of no method for accurately measuring the mineral content of a dietary, but are assured of a sufficient amount when whole-grain products and a variety of vegetables are eaten.

40 East Forty-first Street.

NOTE ON THE STAGES OF TABES DORSALIS.

BASED ON THE STUDY OF 240 CASES.

By MORRIS GROSSMAN, M.D.,

NEW YORK.

ADJUNCT VISITING NEUROLOGIST, CENTRAL AND NEUROLOGICAL HOSPITAL; CHIEF OF NEUROLOGICAL CLINIC, LEBANON HOSPITAL, O.P.D.; ASSISTANT NEUROLOGIST, MOUNT SINAI HOSPITAL, O.P.D.; VOL. ASSISTANT IN NEUROLOGY, MONTEFIORE HOME AND HOSPITAL.

THE conclusions drawn in this note are based on the study of 240 cases of undoubted tabes, taken from my private practice, and the services of Dr. B. Sachs, neurologist to the Mount Sinai Hospital, Dr. S. Wachsman, director of the Montefiore Home and Hospital, and Dr. W. J. M. A. Maloney, neurologist to the Central and Neurological Hospital, to all of whom I am greatly indebted for the privilege of using the material from those institutions.

Preataxic Period.—The preataxic period is that period which occurs between the onset of the first symptom of tabes and the appearance of ataxia. There is no agreement as to the minimum essential to constitute a diagnosis of tabes, and because the development of the ataxia in tabes usually is insidious, and many of the patients do not consider themselves ataxic until they must use a stick to enable them to walk, the preataxic period is extremely difficult to determine precisely.

In a group of 65 cases analyzed and reported by Fournier, the preataxic period in 19 cases was two years or less; in 23 cases, more than two years but less than five years; and from five to fourteen years in 23 cases. In 54 per cent. of Fournier's cases the preataxic period was three years or less.

In my group of 240 cases there were 42 who had no determinable preataxic period. In these patients ataxia came, so far as is recorded, synchronously with, or was, itself, the first symptom of, tabes. The oldest patient in this group was seventy-three years; the youngest was thirty-six; the average age of the group was thirty-nine years. The average age of onset of tabes in this group of 42 cases was forty-four and one-half years.

There were 46 cases that were still preataxic, in whom no ataxia had appeared up to the time they came under observation. The oldest patient in this group was sixty-eight years of age; the youngest was twenty-nine years; the average age for the 46 was forty-two and one-half years. One was still preataxic after 15 years; the average duration of tabes without ataxia in the entire group was 4.39 years. No conclusions regarding the length of the preataxic period should be based on any cases not yet ataxic.

Of the remaining 152 cases 7 could not be estimated, leaving 145. The preataxic period was 2 years or less in 63 (43.3 per cent.) of these 145 cases; in 38 (26.2 per cent.) of the cases, it was more than 2 but less than 5 years, and in 44 (30.3 per cent.) of the cases it varied from 5 to 27 years. In 78 (53.8 per cent.) of the cases the preataxic period was 3 years or less. The average duration of the preataxic period in these 145 cases was 4.14 years.

The following table shows the duration of the preataxic period in the different age groups at which the first symptom of tabes made its appearance:

Age Group of Onset of Tabes.	No. of Cases in the Group.	Average Preataxic Period, Years.
Under 20	2	17.5
21 to 30	26	4.75
31 to 40	57	3.81
41 to 50	48	3.90
51 to 60	12	3.75

In studying the figures in the above table, one sees that the length of the preataxic period diminishes as the age of onset of tabes advances to 40 years and that thereafter it remains fairly constant. The average decrease from the thirtieth to the sixtieth year was 1 year. More data are obviously needed to establish the influence of the age on the preataxic period.

The age of the host does not influence the virulence of the spirochete. Therefore, the shortness of the preataxic period must be determined either by the resistance of the host, varying with age or other factors. From my previous paper, "Statistical Study of Tabes Dorsalis," which appeared in the *New York Medical Journal*, it is evident that the resistance of the nervous system of the host is measured by the pretabetic period, and that this is a factor which may be influenced by age.

Taking these 145 cases I arranged them in sequence, from the shortest preataxic period to the longest the seventy-third case gives the probable

average preataxic period (wahrscheinliche Mittel) of this group; this was 3 years. The arithmetical mean of this group was 4.14 years. In dealing with figures so variable, I believe the probable mean (wahrscheinliche Mittel) gives a more accurate approximation to the true average.

To determine the influence of sex on the duration of the preataxic period was difficult because there were so few female cases in any one group. In 22 ataxic cases, among the females, where the preataxic period was determinable, the average preataxic period, determined by the probable mean, was 2.6 years. The arithmetical mean of the preataxic period in these 22 cases was 3.24 years. In the age group from 41 to 45 years were 21 males and 5 females; the average preataxic period for the males was 2 years by the probable mean method; the arithmetical mean for these 21 cases was 3.73 years. The average preataxic period for the 5 females was 2.8 years, determined by the probable mean method, and 3.34 years by the arithmetical method. Hence the cases indicate, although their number is not sufficient to prove, that women have a shorter preataxic period than men.

The marked variation in the duration of the preataxic period in the same age groups, the difference in the preataxic period in the males and females, suggest that the determining factor may be a psychic one, a mental deterioration that varies in each individual.

Ataxic Period.—Some tabetics long remain ataxic; others have little or no ataxia yet soon become bedridden; and others again perpetuate the ataxic stage. Only in tabetics who become bed or chair ridden on account of ataxia alone may a completed ataxic period be distinguished. Death, joint changes, and injuries must be looked upon as accidental terminations of ataxia.

In this series of 240 cases there were 36 (15 per cent.) who became bed or chair ridden; of these 6 cases have been immobile for one year or less; 6 for more than one year but less than three; 12 for from three to four years; 4 for more than four years but less than eight years; 4 from eight to twelve years. Twenty of these cases have been immobile from three to twelve years, yet two to four years is commonly alleged to be the life expectancy of the bedridden tabetic.

The remaining 4 of these immobilized patients died; one at the age of 39 after 3 months of immobilization; one at the age of 30 after being bedridden 4 years; another at the age of 50 who had been bedridden 12 years, and the fourth at the age of 49 after being immobilized 7 months. Maloney points out that the duration of the bedridden period is mainly determined, not by the disease, but by the nurse.

Among these immobilized tabetics are three main groups. The first comprises 16 cases immobilized by ataxia complicated by injury, resulting in fractures or Charcot joints. The second group consists of 5 cases of optic atrophy, resulting in almost complete blindness, with or without injuries. The third group includes 15 cases immobilized by ataxia alone.

Among the 16 ataxics forming the first group immobilization followed in 5 cases the occurrence of blindness and ataxia; in 5 others, the appearance of Charcot joints; immobilization was twice attributed to fracture and Charcot joints; once to fracture without joint trouble; once to intraspinal medication; once to perforating ulcer of the foot, and once to muscular atrophy complicating ataxia. Only in the case which was bedridden because of muscular atrophy could a real paralytic stage be distinguished.

Of the 5 cases in the second group, none have had ataxia. Three took to bed and remained there after injury to their lower limbs, and two after the onset of blindness.

Of the 15 cases immobilized because of ataxia alone, one retired to bed immediately ataxia appeared; 7 became bedridden within 4 years, two cases within 6 months, one 12 months, one 18 months, one 24 months, and two 42 months after the appearance of uncomplicated ataxia; in the remaining 7 cases the duration of the ataxia varied between 6 and 15 years.

The average age of these immobilized patients was 53 years.

It is useless to discuss the duration of the ataxic periods in those who from Charcot joints, injury, blindness, or other accidents became bedridden. One might as well discuss the average duration of active life from a series of cases immobilized by street accidents. The only cases upon which any conclusions may be based are those fifteen which became immobilized on account of uncomplicated ataxia.

The following is a table of the 15 cases, bedridden from uncomplicated ataxia, showing the duration of the preataxic period, ataxic period, bedridden stage, and the age of onset of tabes in these cases:

Age of Onset of Tabes, Years.	Duration of the Preataxic Period, Months.	Ataxic Period Before Immobilization, Months.	Bedridden Period, Months.
41	None	77	7
52	None	180	60
29	None	84	48
39	None	117	3
52	3	6	18
24	6	18	48
33	12	None	72
48	30	6	12
33	30	24	18
45	48	42	30
36	48	72	1
40	60	132	36
30	60	144	132
49	72	66	66
30	84	12	144

From this table it is obvious that in these cases there is a conspicuous tendency to a short preataxic period; seven of the fifteen cases became ataxic within one year after the onset of tabes. The probable average preataxic period determined above was 3 years; therefore 46.6 per cent. (7 out of 15) had one-third the normal preataxic period or less, and 60 per cent. (9 out of 15) had less than the probable average normal.

Five of the 15 patients became bedridden within 18 months of the onset of ataxia; indeed, one retired to bed immediately the ataxia appeared. The average duration of the ataxic period in this group of 15 cases, the only cases from which the ataxic period can be correctly estimated, was 4.11 years.

The usual conception of a bedridden stage, habit-

ually occurring 10 to 20 years after ataxia has appeared, is therefore erroneous. Only 3 (20 per cent.) of the 15 bedridden cases, due to ataxia alone, occurred later than 10 years after ataxia appeared.

Maloney has divided the ataxic period into four stages: the biped stage, when locomotion is still unaided; the tripod stage, where only one stick is used; the quadruped stage, where two sticks are necessary for locomotion; the chairridden stage and the bedridden stage, which is the final stage of deterioration of attitude. This subdivision represents deterioration of attitude without regard to the extent or severity of the tabetic lesions.

The average preataxic period of these 15 cases was 2.53 years. It is remarkable that of 6 cases who became bedridden within 2 years of the onset of ataxia the preataxic period in 5 of these cases was 1.5 years, half of the probable average 3 years (as determined above); in only one of these 6 cases did the preataxic period exceed this average.

Maloney contends that the deterioration of attitude is mainly a mental and not a structural deterioration. The short ataxic period in these bedridden cases, according to Maloney, is due to the same mental inferiority which conduced to the short preataxic stage. Further support for this contention is obtained by the examination of the individual cases in this group. Thus Case 177, an ambulant ataxic, through the shock of the death of her daughter took to bed and has never walked since, a period of 6 years. Case 108 had been ataxic for 18 years; 7 years ago he had a perforating ulcer of the sole of his foot; he took to his chair, and although the ulcer has been healed for almost 7 years he has never again attempted to walk. Case 88 had a sudden giving of the knees 6 years ago and has never walked since. I could cite other analogous cases from this group, but I think these three adequately illustrate the mental influence in the deterioration of attitude among tabetics.

The exclusively ataxic cases seldom became bedridden, but they tended to perpetuate their ataxia. If added to ataxia, there was trauma, either simple, or resulting in fracture, joint trouble, shock, or despair, deterioration of attitude was likely to occur. The psychic influence of blindness was also a prominent factor in reducing these patients to hopelessness and helplessness; indeed, in 5 of the cases, blindness in itself was sufficient to cause immobilization when there was no existing ataxia.

Conclusions.—1. The duration of the preataxic period may be influenced by age.

2. The probable average preataxic period is three years.

3. Women seem to have a shorter preataxic period than men.

4. The average life expectancy of the bedridden tabetic is very much longer than that usually taught.

5. The average age of the immobilized tabetic is 53 years.

6. Most tabetics usually perpetuate the ataxic stage; in the small percentage of cases which become bedridden, owing to uncomplicated ataxia, the average duration of the ataxic period is 4.11 years.

7. Among those who become bedridden a short ataxic period usually follows a short preataxic period. This substantiates Maloney's contention that the deterioration of attitude is mainly mental and not structural deterioration. The short ataxic period in these bedridden cases is due to the same mental inferiority as is conducive to the short preataxic stage.

SOME POSSIBILITIES IN THE TREATMENT OF THE TUBERCULOUS INSANE.*

By NEWELL B. BURNS, M.D.,

North Wilmington, Mass.

Assistant Superintendent North Reading Sanitorium.

In electing to discuss the subject proposed in the title of this paper, I find that I have rushed in where men of greater experience hesitate to tread, but if the proposed possibilities appear too fanciful or impractical for adaptation to the management of the insane, I trust that it will be understood that the suggestions arise wholly in my enthusiasm for the principles of Sanatorium Treatment of Tuberculosis.

First to be considered is the *detection* of tuberculous disease among insane. On admission, the patient's history, of antecedents and of past and present illness supplemented by information from friends and relatives, should disclose facts pointing to tuberculosis, *if such exists.* Physicians admitting patients are apt to follow their respective hospital inquiries too closely, neglecting a wider range of possibilities in the patient's previous illnesses. It is important to know about his general state of health for *some time before* he was sent to the hospital, if we are going to look for tuberculosis in this newly admitted patient.

It has been estimated[1] that one-quarter of the tuberculosis which appeared in patients in a group of hospitals for the insane over a given period of time, was present at the time of admission. The three-quarter portion was contracted within the institutions. The history is especially important, then, for in a large number of cases very little cooperation may be expected from the insane patient in the physical examination. There is, then, a large field for the use of diagnostic methods of which tuberculin is notable, as well as the *x*-ray. Wherever evidence of possible active tuberculosis needs confirmation, the use of tuberculin subcutaneously is valuable. Some skill is necessary in applying this diagnostic method, without which skill, disappointing and disastrous results have occurred. Rapid loss of weight and vesperal fever are sometimes late symptoms, and too much reliance upon their absence would allow a tuberculous patient to go unnoticed for some time.

All cases of diarrhea which persist over the winter are to be regarded as suspicious of tuberculosis, and if afebrile should receive diagnostic injections of tuberculin.

A course of tuberculin for diagnostic purpose.[2] It is best in adults to give an initial dose of 1/10 of a milligram, take the temperature every two hours for a period of two days, and if the patient fails to react, to follow this injection with successive

*A contribution to the William Leonard Worcester Memorial Series of Danvers State Hospital Papers, presented November 19, 1915.

doses of 1, 3, 5, and 7 or 10 milligrams, similar observations on the temperature being made for an equal period between each injection. An initial dose of 10 milligrams may be followed by dangerous and even fatal consequences.

Another method, together with certain deductions and limitations of the tuberculin test for diagnosis, may be found in Park & Williams.[10]

The contraindications to the subcutaneous test are, certainty of diagnosis, fever, recent hemoptysis, advanced heart or renal disease, epilepsy, diabetes, and convalescence from a severe infection.

In a certain large, well-managed public institution, 60 per cent. of the deaths for a period of twenty-one years came to autopsy. The autopsies numbered 2102 and in 20 per cent. there was found active tuberculosis.[6] Latent tuberculous lesions were found in still larger number. In an unpublished report by Southard of the autopsied cases in certain of the State Hospitals in Massachusetts, there were 149 unknown cases of tuberculosis in a total number of 3831 autopsies. Therefore, it is advisable to add the constitutional reaction of old tuberculin.

There seems to be a high correlation between dementia præcox and tuberculosis. Forty-two per cent. of the deaths from tuberculosis in all the Massachusetts State Insane Hospitals in 1905 were dementia præcox cases.[2] There is an *age of onset* coincidence in the two diseases, and furthermore, such demented and untidy patients with the nutritive disorders associated with dementia præcox and allied mental disorders probably are more susceptible to infection. This group of insane patients would bear closer scrutiny. More trustworthy patients are able to obtain daily out-of-door exercise, which appears to be the best prevention against tuberculosis among the insane. If there were opportunities for open-air exercise for female patients to the same extent as for male patients, the female tuberculosis mortality rate would probably be less. It is now far in excess of the rate for males.

The Section on Psychiatry at the 13th International Medical Congress, Paris, 1900, voted a measure favoring the isolation of the tuberculous insane and their treatment in special pavilions. It was brought out by Marie that German institutions had already established this practice, following the decision of the Congress of Berlin in 1899, and that for the purpose a so-called asylum-sanatorium type was set up at Lauenbourg. In Italy[4] all admissions were subjected to diagnostic tuberculin and suspicious cases isolated in a distinct pavilion. Marie[3] calls attention to the necessity of examinations of military strictness for all employees of institutions for the insane in the work of thoroughly eliminating all possible sources of tuberculous infection.

In 1908, Dr. H. Declerc[5] stated, "Since tuberculosis, now a contagious malady, has so powerful an effect on certain psychoses it is necessary to isolate at first for the treatment of the individual patient, and furthermore to avoid its dispersion; this will be the work of sanatoria." This author devotes his paper in the main to discussing the means of diagnosing tuberculosis upon the insane wards and recommends tuberculin as a precise means, finding that the physical examination often fails to show up this disease.

In America, Hutchings,[6] Carrington,[7] and other authors, have discussed the need for isolation. Dr. A. E. McDonald, director of the Manhattan State Hospital, speaking of his own experience in this practice, stated, "The isolation of the tuberculous patients has reduced to a minimum the danger of infection of other patients, *and of employees*. The patients themselves have suffered no injury or hardship but have, on the contrary, been unmistakably benefited."[11] A segregation unit is possible in Massachusetts with a transfer arrangement of tuberculous patients. With some definite system in operation, isolation should be as utterly complete as is possible. Under the present circumstances we hear that segregation "was more or less completely accomplished." The present-day need is to eliminate the words "more or less" and to make segregation as absolute as human means can devise.

A classic example of what segregation[12] can accomplish appears in the the experience of the State of Alabama in 1895-1902. Mortality from tuberculosis among the insane negroes in custody reached 51 per cent. Segregation in a special unit at Mount Vernon reduced this rate to 22 per cent. and kept it down. The rate for whites dropped from 39 to 9 per cent., due to the relief from overcrowding and to the isolation of the tuberculous insane.

Lately there were developed special units for the tuberculous insane in Florida, Kentucky, Wisconsin,[9] and Iowa.[8] Some New York institutions for a number of years have maintained tuberculosis pavilions to which other hospitals transfer patients for treatment. These institutions have almost uniformly reported a decrease in the prevalence of tuberculosis, some characterizing it as a remarkable decrease. The smaller cottage types of open wards with spacious verandas are preferred to the larger ward buildings. An abundance of fresh air, sunlight and absolute cleanliness must be remembered in planning construction, not only to protect the attendants but to aid in the recovery of the sick.[10] In the long run, tents are too costly and unsatisfactory, and should not be considered for more than temporary housing. This is our experience at North Reading.

The practice of New York in transferring their patients from one hospital to another, as mentioned in the foregoing, affords some explanation for the baffling nature of statistics concerning the tuberculosis mortality rate among the various institutions. Comparisons based upon this data are unfair, either in New York State or Massachusetts.

The record of the Bureau of the Census published in 1914 dealing with "The Insane and Feeble Minded in Institutions" for 1910, reports: "The proportion of deaths caused by tuberculosis of the lungs is almost the same for the insane as it is for the total adult population, 12.9 per cent. of the total deaths in one case and 12.5 per cent. in the other." Analysis of this report adds very little of importance to this discussion, and the only fact of interest is that the mortality rates for tuberculosis among the insane vary widely. The probable responsible causes in those instances of variance into which inquiry was made, are not those expected, and so afford very little explanation why there should be more tuberculosis in one division of hospitals than in another. Such explanation, if af-

forded, would perhaps suggest remedies. Therefore, what seems necessary in the published reports is a *tuberculosis morbidity rate.* This would indicate how much tuberculosis was developing in each hospital and would obviate misleading conclusions, such as are now apt to be formed. A problem could then be worked out as to how many patients, who are discharged yearly from state hospitals for the insane, contracted tuberculosis in these hospitals; or perhaps took the disease home and out into the community.

In 1911 a canvass[15] of the State hospitals for the insane in the United States showed that 28 States were then making provisions for their tuberculous insane in special wards, tents, pavilions, or by some form of isolation. The total capacity for this purpose amounted to 3492 beds. The total number of the insane in custody of State institutions in 1910 was 187,791.[16]

Massachusetts' special provisions for the isolation, actual and partial, of the tuberculous insane consisted in 1911 of 180 beds, or for 1.5 per cent. of total patients, 11,601. (1910).[15] Corresponding figures for the State of New York were 1020, or 3.2 per cent. of total patients, 31,280.

At the international congress in 1899 in Berlin Dr. F. Liemens in discussing the care of the tuberculous insane, described the arrangements at the Asylum-Sanatorium in Lauenbourg.[17] Two wards, or barracks, for men and women respectively, were constructed in 1896, each of 25 bed capacity, for sums equivalent to $5,000 each.

They were sitated in open spaces amidst pine woods at a considerable elevation. The open wards were not unlike the usual sanatorium construction of to-day, but the rooms for the disturbed tuberculous patients were uniquely planned. That is, there were many windows of thick glass placed high up on the walls; sanitary bases, terrazzo floors, and smooth enamelled walls; the construction being so planned as to obtain a maximum of sunlight, of fresh air and of scrubbing brush opportunities.

Finally, since the business of segregating and caring for tuberculous patients of any sort, presents difficult problems in itself, how is it fair to expect much if the management of the insane is to be handicapped by this added responsibility? Segregation in separate units is one idea for consideration among the possibilities of solution of this practical problem.

Medicolegal Notes.

Malpractice—Insufficient Evidence of Negligence.—In an action for malpractice consisting of performing an operation for appendicitis and diseased ovary while the plaintiff was pregnant there was no evidence that the defendants were incompetent or unskillful surgeons, nor was there any claim that the operation itself was not performed in a skillful and proper manner. The charge was that the defendants negligently advised an operation. In this kind of a case the plaintiff must not only prove that the operation was unnecessary, but also that it was so palpably unnecessary that a surgeon of ordinary care and skill would not have advised it. If conditions were such as to lead surgeons of ordinary care and skill to think an operation was necessary, and the defendants, in the honest exercise of their best judgment, thought an operation was proper, then the defendants would not be liable even if it turned out afterwards that they were mistaken in their diagnosis. The burden was on the plaintiff to establish the negligence charged; hence it devolved upon her to show that the operation was one which surgeons of ordinary care and skill in the honest exercise of their best judgment would not have advised.

All the doctors who had seen the appendix and ovary which had been removed from the plaintiff united in saying that both were diseased, and all of them, some half a dozen or more, pronounced an operation upon a pregnant woman for their removal to be advisable and proper. The plaintiff introduced no testimony to show that conditions were not as the defendants said they were, and she did not deny that she told the defendants she had had several miscarriages. The evidence was held insufficient to take to the jury the question whether her condition was such that an ordinarily skillful surgeon would have known that an operation was not necessary.—Fausette v. Grim (Mo.), 186 S. W. 1177.

Qualification of Applicant for Examination for Certificate.—The Rhode Island Supreme Court holds that one who does not claim to be qualified to pass an examination by the state board of health as to his fitness to practice medicine, but claims the right to practice a new system of healing originated by himself (the defendant styled himself a Neuzopath), cannot question the constitutionality of the Rhode Island statute of 1909, which requires an applicant for examination to be a graduate of a medical school, on the ground that such provision excludes persons qualified in other respects to pass an examination. While the practice of medicine was in the beginning empirical, and while different schools still differ as to proper treatment for diseases, the profession has in the course of its years of practice acquired a large fund of exact knowledge on the subject of the human body and of healing agencies, so that it is so improbable that one who is not a graduate of a medical college could discover an entirely new system of healing unknown to any student that the provision of the statute, which impliedly excludes the practice of a system of medicine not taught in any medical school, cannot be held contrary to the constitution that a person shall not be deprived of his liberty or property without due process of law, on the ground that it is not reasonable to require such qualification for applicants.—State v. Heffernan (R. I.), 100 Atl. 55.

Military Medicine.

SOME REFLECTIONS ON THE SURGERY OF WAR, VIEWED AFTER THREE YEARS.

By CHARLES GREENE CUMSTON, B.S., M.D.,

GENEVA, SWITZERLAND,

PRIVAT-DOCENT AT THE UNIVERSITY OF GENEVA; HONORARY MEMBER OF THE SURGICAL SOCIETY OF BELGIUM; FELLOW OF THE ROYAL SOCIETY OF MEDICINE OF LONDON; MEMBER OF THE SURGICAL SOCIETY OF SWITZERLAND, ETC.

THE following desultory remarks are offered to the men who are to take the field and have so far remained in the United States, far from the centers of action. It will be evident that what is to follow is merely a very incomplete summary of the present surgical situation, but it may in a few words give a general idea of practice at the front.

The surgery of warfare so greatly differs from what surgeons have been used to that it was at first a surprise to all to encounter so great a number of cases that civil practice had insufficiently known. Unquestionably the great surgical principles remain unchanged, but the very nature of the wounds of warfare, the reactions of the injured, and the surroundings in general, created absolutely new conditions for which adaptation was necessary. But this requisite adaptation rapidly took place, and a new war surgery has resulted, doing away with all the theories of gunshot wounds formulated as a consequence of the Russo-Japanese and Balkan wars.

The first fact which has been acquired is that most wounds or injuries are due to rifle bullets, grenades, bursting shell, etc., and that bayonet wounds are very rare. In some of my lecture notes, published in the *Boston Medical and Surgical Journal* and in the *New York Medical Journal* at the beginning of the war, I at the time prognosticated that such would be the case, because fighting with bayonets in hand-to-hand struggles would be limited in extent, and also because a bayonet wound would be more likely to be driven home in the abdomen or thorax, thus wounding the important structures and blood vessels particularly, with instantly fatal results, and such has been the case, with, of course, some few exceptions, particularly so far as the limbs are concerned.

Another point to which attention should be called is the almost invariable infection of wounds. *Every wound, with the exception of a "seton shot," must be looked upon as infected from the start.* A rise in temperature will be present within a few hours after the injury, the index of a commencing septic process. The etiological factors of wound infection in war are legion, but injuries resulting from a spent bullet or bursting shell are invariably soiled with earth and bits of clothing, the latter containing in its meshes numbers of anaerobic bacteria, the former containing the tetanus bacillus.

Very frequently the medical post on the firing line is so encumbered during action that only summary attention can be given to many injuries, while the transport of the injured in such great numbers, often under the most adverse conditions, is among the multiple but unfortunately unavoidable causes favoring infection.

Within a few days, not infrequently within twenty-four hours of proper treatment at a hospital or ambulance at the rear, a rapid improvement becomes visible in many severely injured. After a few days of rest and calm the temperature reaches the normal, and for this reason it is incumbent for the surgeons at the front to get their wounded to the rear in all cases where the patient will be able to bear the transportation.

It may be said in a general way that wounds in warfare suppurate until their complete cicatrization, regardless of the most minute aseptic and antiseptic treatment. The causes are the very nature of the injury, in the first place. The entrance and exit openings of a bullet which has gone through a limb have a decided tendency to close, often within a day or two after receipt of the injury, while the tract still contains foreign bodies of all sorts, particularly bits of clothing. If the bone has been injured, splinters will be present in the traumatic focus, and those detached from the periosteum will act as foreign bodies and increase the progress of infection.

Bullets and pieces of shell or shrapnel shot frequently become encysted without producing any disorders if they do not involve a nerve trunk or large blood-vessel. But with the exception of bullets these foreign bodies practically always carry dirt and bits of clothing into the wound, and these cannot be diagnosed, but it must be taken for granted that they are there. Therefore, *every* wound must be freely opened, exposed, and all foreign bodies removed.

Besides projectiles, one often finds other foreign bodies in the wound, such as buttons; and I know of a case of a large abscess on the thigh from which, after incision, the remains of the soldier's watch were removed.

Given these septic lesions, it is evident that antisepsis is to be relied upon much more than in civil practice. Carbolic acid is an excellent antiseptic, but has now been given up, very largely on account of poisoning, which was particularly noted by English and Canadian surgeons. Dakin's solution is of value, and should be employed in spite of much adverse criticism to which it has, and I think most unjustly, been subjected.

I am of the opinion that ether is a very superior antiseptic, and its use in peritonitis and large injuries to the joints and limbs, I can confidently recommend. It is indicated in vast cavities which are not easily drained, such, for example, as compound fractures of the thigh. Space does not permit me to consider many other excellent antiseptics, but I would particularly mention irrigation with a 1:200,000 silver nitrate solution according to the method of Denyze, when disinfection combined with stimulating action is required.

Correct statistics can only be made after the war is over, but certain facts are nevertheless striking. Unquestionably vast fracture wounds are the most common, and it is also evident that since the use of Adrien's metal helmet injuries of the skull and brain have decreased quite notably.

In order of frequency, fractures of the thigh come first, after which come those of the leg and humerus. I am also of the opinion that fractures of the leg more frequently escape the effects of conservative treatment and necessitate amputation,

and after them come fractures of the thigh. Fractures of the humerus seem generally to consolidate quickly after proper immobilization has been obtained.

Open fractures of the femur always seem the most serious at first, because the vast wound is usually accompanied by a focus difficult to drain, but if muscular contraction is overcome, and carefully guarded against, the prognoses in many cases will not prove to be as bad as when the case was first seen. On the whole, amputations of the thigh have not been considerable during the war.

After free exposure of the wound focus and removal of the bone splinters and foreign bodies, if the suppuration is free and the fracture easy to keep reduced, some simple splint may be all that is required in *some* cases, but the best results are unquestionably obtained by extension apparatuses. Of course, when the wound needs frequent daily dressing. the plaster-of-Paris collar splints, with galvanized-tin joining brackets, are the only type to be employed.

When the suppuration continues, and shows no inclination to diminish in infected cases, with a progressive decline of the patient's general health from the sepsis, the question of amputation comes up for consideration. It is better to be conservative in regard to removing a limb, and it is better to temporize within the limits of safety, because we have all seen cases in which amputation was judged necessary by some, but the patients recovered with their limbs, although not in perfect condition, still with a consolidation that was quite acceptable.

Wounds of the thorax and abdomen, naturally penetrating ones, require more space than I can give, but I may say that, contrary to what was thought at the beginning of this war, most surgeons are now convinced that when one can operate in proper surroundings a laparotomy should be done at once, even in an ambulance behind the line, and results have justified this conclusion. Penetrating wounds of the thorax involving the heart or lung constitute a subject too long to be discussed, but I would say that at the ambulance, after cleaning the surrounding skin, a very tight binder should be applied, morphine given to ease the dyspnea, and the case then watched for further developments.

It is astonishing how well a large percentage of thoracic wounds do. Empyema is very prone to occur, but resection of one or two ribs and pleurotomy have usually mastered the situation, even when it appeared desperate.

3, Rue Belot.

PARATYPHOID AT THE FRONT.

Since 1896, when Achard and Bensaude described a case of clinical enteric fever which showed an organism other than typhoid in the urine, paratyphoid fever, the name they gave to this new clinical entity, has been the subject of considerable study. Before the war, it has been estimated that it occurred in about three per cent. of all cases of the kind which were formerly diagnosed as typhoid. During the first part of the war, there were a large number of cases of paratyphoid B in Belgium and Northern France, later on the A type also became prevalent. The health reports from the Gallipoli campaign show a large prevalence of paratyphoid, also. The reports available from the German army and navy do not report paratyphoid separately, but give an incidence of typhoid fever in the army of 5.6 per 1,000 and in the navy of 0.17 per 1,000.

The importance then of a complete knowledge of this disease can hardly be questioned. The Goulstonian lectures, delivered before the Royal College of Physicians of London by Dr. C. H. Miller (the *Lancet*, May 19 and June 2, 1917) are singularly appropriate, giving as they do an elaborate survey of this disease. Dr. Miller describes eight types of it: (1) the typhoid type, which is the most common; (2) the dysenteric type; (3) the biliary type; (4) the nephritic type; (5) the "rheumatic" type; (6) the respiratory type; (7) the influenzal type, and (8) the septicemic type. It seems probable that, as in so many other instances in the early history of a disease, we have here too great a tendency to classification; probably the future will see described only one kind of paratyphoid with a various symptomatology and numerous complications.

We can, of course, touch only upon the high lights of Dr. Miller's treatise. He considers the subject quite exhaustively, not from a didactic standpoint, but in the light of clinical experience obtained at the front, having been a Major in the Royal Army Medical Corps. His observations were made at the British Red Cross Hospital, Netley, where patients are received from every front. An interesting fact was that seldom were they admitted with a diagnosis of enteric; their symptoms began either a few days before or a few days after admission. "Men who have been buried, or gassed, or who had trench feet or wounds of the chest seemed particularly liable to contract the infection."

Miller not only describes eight varieties of the disease himself, but he expressly states that there are probably other kinds which other observers have seen and says that these must be added to his account before we have anything like a complete description of the disease. Paratyphoid fever is a great imitator of other diseases and it also seems to have the faculty of rendering active in an individual other diseases which had been for the time being latent, such as rheumatism, tuberculosis, and the like.

In conclusion, Miller gives it as his opinion that paratyphoid fever, frequent as it has been, is going to increase, and, therefore, inoculation against it is imperative. A strictly hygienic handling of the cases themselves is taken for granted. There is a tendency at the front at present to regard every case of unexplained pyrexia as paratyphoid; that is an extreme state of affairs, but, on the other hand, undoubtedly many cases in the so-called epidemics of influenza or gastric catarrh should be carefully scrutinized lest they should prove to be paratyphoid.

LETTERS FROM AN M. M. R. C.

It is somewhat a shock for a man who has been brought up in polite surroundings to have his first introduction to regimental life made at noontime mess—or any other for that matter. His mind gropes for something to liken it to, and the nearest approach would be the remembrance of witnessing convicts eating in prison or perhaps a badly run boarding school with the masters out of the room. The utensils used at table consist of a large enamel

cup which is used for either lemonade, coffee, or iced tea as the case may be; then there is an enameled pie plate on which your food is dished in the kitchen and placed before you, and the drink, whatever it is, is placed in large enamel pitchers on each table, and those in between find their time kept busy passing such things that are yelled for in every form of military intonation. Quite a number of those in camp are doctors who served recently on the Mexican border attached to some State militia. Being on the Medical Reserve Corps, they are obliged to go through the same training as the rest. Among the others we find the doctors we are most interested in—those who have just come from private practice for whose instruction these letters are particularly written. These men represent the elderly men of the barracks. Their ages run from forty to fifty-five years. To them this is all new life and experience. They are the ones who for the most part answered the call for purely patriotic reasons. There are a good many stories of more or less pathos of these doctors who have come together to help their country. Many have left behind motherless children of tender years and no relatives to look after them. As a whole these men are giving their entire careers freely to the Government to do as it sees fit with.

As to habits, there is no attempt made to evade the letter of the law, and I doubt that a single officer can be found who has had a single drink of alcohol since he entered training camp. The subject is not mentioned. In the middle of a long hike or drill, no one says: "Oh, how I'd like a rickey," but instead, "I could drink a bucket of lemonade!" This is not the exceptional case in one barrack. It is the rule of all. To those doctors who are accustomed to daily tippling I should without hesitation recommend them to join at once. It need not be called "swearing off." It's an impossibility to get it as long as you wear the uniform and you have to wear the uniform if you are in service.

The uniform and equipment kit will cost nearer three hundred dollars than two hundred. This must come out of one's own pocket and must be bought before one goes on active service. The regulation equipment would be considerably cheaper if one could buy these things from the commissary department, but it is impossible, for this department has run out of many of its supplies. This drives the officer to purchase elsewhere, paying three times what it would cost if purchased from the Government. For instance, woolen socks which the quartermaster sells at thirteen cents a pair are often out of stock and the soldier has to pay fifty cents for socks at the post canteen. Regulation shirts should be about $2.50 at quartermaster's. The same are $4.50 when bought at canteen.

To go back to the new arrival in the medical officers training camp. You will see in your pamphlet that you should appear before the adjutant with "side arms." Don't do it unless you wish to cause a burst of unrestrained merriment among your future messmates. Given a hot day (and every day is a sweltering one now in army encampments), the officer's uniform blouse buttoned tightly up to neck and a heavy handbag that you have to tote—now add to this a sword which is doing its best to trip you up and an army revolver. Among the thirty thousand in camp you will be the only "real guy" and it will never be forgotten! You will notice as soon as you arrive that no one except yourself wears the regulation army coat or blouse that is worn in the cities. In camp you can wear only the regulation army cotton shirt. You do not wear the insignia of your rank. On the collar of the shirt the only thing necessary is the caduceus and the U.S.R.—the caduceus on left lapel and U. S. R. on right. The cap with visor worn in city is never used in camp, but always the felt hat. Get this the regulation shade of brown—not a green or pearl gray as you may be shown. The necessary equipment will be taken up in another letter.

As to the rule of not wearing your insignia of rank while in training camp, although there is no law against it, it is considered very poor form. To all intents and purposes while you are in training camp you are all of the same rank. The lieutenant gets as much consideration as the major who sleeps in the cot alongside of him. If the major snores too loudly at night the lieutenant alongside is quite within his rights if he shakes him. The captain of your company may only be rated as lieutenant in the army. He, nevertheless, is your captain and you have to obey him as he does his major. Do not think that exalted rank will give you any leeway. Every man is judged on his own merits of the present. No one discusses his practice or what an important person he was in his own home town. No one is pointed to as "There is so and so, the well known surgeon of so and so." The men all address each other as "Doctor" even when their military title is known. The war as it progresses in Europe is hardly ever spoken of by the men. They all look confidently forward to taking active part in either France or Russia. The idea of being stationed at home or sent to the Philippines to relieve others from duty is loathsome and is at once dismissed as an impossibility of injustice at the hand of the Government. Many men who were connected with hospital units before they came to training camp now regret the step and are doing their best to free themselves. They rightly feel that they would rather work directly under the War Department of the United States Army than indirectly through a hospital unit. There is no doubt but this is the best thing to do for the man wishing for advancement.

Good Health of United States Troops in France.—A cablegram from the American Training Camp in France to the Associated Press states that the hard training work for the trenches is proving a veritable tonic to the American expeditionary force. The percentage of illness for the entire force is only 2½ per cent. as against an average of 5 per cent. in army posts in the United States. Nearly all sickness is made up of light cases of mumps, measles, and colds. This is very gratifying in view of the fact that the medical staff is shorthanded at the present time. It is stated that the American army has only one doctor and eleven medical corps men to each 800 soldiers. The French have two doctors and thirty-seven medical corps men to the same number of soldiers and find this staff none too large.

French Hospitals Turned Over to Americans.—

The French authorities have turned over two large military hospitals and a large medical depot to the Medical Corps of the United States Army. American base hospital units are maintaining these institutions. The entire American expeditionary force has been inoculated against typhoid and paratyphoid. A large field laboratory is in the process of construction near the American training camp.

Air Raid on French Hospital.—During a German air raid recently four bombs were dropped on a Red Cross Hospital, killing two doctors, a chemist, and a male nurse. A third doctor and several patients were injured. Two women were also injured in this raid. It is said that the airplanes were flying so low that the pilots could not possibly fail to distinguish the red cross painted on the roof of the hospital.

Changes in Defense Council's Medical Board.—The Council of National Defense announces that more than one-half of the original membership of the general medical board of the Council of National Defense have entered the service of the Army or Navy, and are now engaged in active work for one of the military departments, either abroad or in the United States. This has resulted in a number of changes in the membership of the board. The members who have been called to active duty in the offices of the Surgeon Generals of the Army and Navy include: Drs. William J. Mayo, Rochester; Victor C. Vaughan, Ann Arbor; William H. Welch, Baltimore; Theodore C. Janeway, Baltimore; W. H. G. Logan, Washington; Edward Martin, Philadelphia; Charles H. Mayo, Rochester; William F. Snow, New York; Stuart McGuire, Richmond; Winford Smith, Baltimore; William C. Woodward, Washington. The following are in service in France or elsewhere: Drs. Frederic A. Besley, Chicago; George E. Brewer, New York City; George W. Crile, Cleveland; John M. T. Finney, Baltimore; Joseph Marshall Flint, New Haven; Charles H. Peck, New York City; Richard P. Strong, Boston; William S. Thayer, Baltimore; George Walker, Baltimore.

Reorganization of the Medical Service in the Cuban Army.—Owing to the declaration of war against Germany, Cuba has decided to increase her army to 17,000 men. The medical service is being reorganized, and one colonel and twenty more officers of lesser rank will be commissioned.

New Bureau of Sanitary Service.—The War Council of the American Red Cross has established a Bureau of Sanitary Service under the direction of Dr. W. H. Frost. An appropriation of $800,000 has been made for the use of the bureau. This step has been taken in order to meet the new conditions which will arise as a consequence of bringing together so many men as will be mobilized throughout the country. The Bureau of Sanitary Service will supervise and aid in such operations as will tend to make health conditions about the camps as nearly ideal as possible. Increased forces will be provided for milk inspection, war will be made on malaria-carrying mosquitos, and a radius of from fifteen to sixty square miles outside of camps will be policed for the protection of the health of the men. Sanitary units will be furnished to the areas upon the request of the civil authorities.

Canadian Hospital Ship on Rocks.—A Canadian hospital ship with 546 wounded soldiers on board was stranded during a fog in the harbor mouth off Halifax. All the wounded soldiers were safely transferred to the Pier Hospital in Halifax Harbor.

National Surgical Dressings Committee Becomes Auxiliary of American Red Cross.—The Red Cross War Council announces that the National Surgical Dressings Committee has become an auxiliary of the American Red Cross. This arrangement has been perfected after protracted negotiations between Mrs. Mary Hatch Willard, the organizer and chairman of the Surgical Dressings Committee, and Judge Robert S. Lovett, chairman of the Red Cross Committee on Co-operation. It is believed that this is the precursor whereby other war relief organizations may become allies of the Red Cross. The arrangement with the Red Cross provides that the Surgical Dressings Committee shall retain its name and organization and carry on its present work in the United States as a national auxiliary of the Red Cross organization.

Committee of Women Physicians to Assist in War Work.—The Council of National Defense has added to the general medical board a committee of women physicians. It is felt that women physicians can accomplish much in the way of anesthesia, laboratory work, and sanitation. Plans are now being formulated under which the new committee is to act. The committee appointed consists of Dr. Rosalie Slaughter Morton of New York, chairman, and Drs. Caroline M. Purnell of Philadelphia, Caroline Towles of Baltimore, Florence N. Ward of San Francisco, Mary Lapham of Highlands, N. C., Cornelia C. Brant of Brooklyn, and Marion Craig Potter of Rochester, N. Y.

Red Cross Hospital for Navy.—The American Red Cross has established at Philadelphia, for the use of the Navy at the present time, the first general Red Cross Hospital in this country. Philadelphia has offered the Medico-Chirurgical Hospital to the Red Cross for an indefinite length of time without rental. The Red Cross has undertaken to alter and reconstruct the building and has appropriated $20,000 for its current expenses and maintenance. The institution contains about 250 beds, and will be known as Red Cross General Hospital, No. 1.

Rockefeller War Hospital Opened.—The Rockefeller Institute made an official visit of the Surgeon General and the head of the Medical Bureau of the Council of National Defense, on August 12, the occasion for the formal announcement of the opening of the institute's war demonstration hospital. In addition to Surgeon-General Gorgas and Dr. Martin and their staffs, a large number of army and medical reserve officers, Colonel Goodwin, medical member of the British War Mission, and representatives of the French Medical Service were present. Dr. Flexner told what the institute hoped to contribute to the American Service and other experts gave demonstrations in the treatment of wounds by the Carrel-Dakin method and the methods of treating "gassed" soldiers. On this occasion it was also stated that the serum for gas gangrene, the discovery of which was announced some time ago, had reached a stage of development where it was considered safe to use it on humans. The visiting surgeons also inspected the Columbia War Hospital.

APPLICATION FOR APPOINTMENT IN THE MEDICAL RESERVE CORPS, UNITED STATES ARMY

.....

....., 191

To the Surgeon General, U. S. Army,
Washington, D. C.

Sir:

I hereby make application to be examined for appointment in the Medical Reserve Corps, U. S. Army, and inclose testimonials as to my character and habits.

I certify that to the best of my knowledge and belief I am laboring under no mental or physical infirmity or disability which can interfere with the efficient discharge of any duty which may be required of me if appointed in the Medical Reserve Corps, U. S. Army, and that the answers given to the interrogatories below are true and correct in every respect.

I furthermore state my willingness to proceed to such point for examination as may be designated by the Surgeon General, with the understanding that the journey entailed thereby must be made at my own expense.

INTERROGATORIES

Where were you born? (Give State and city or county; if foreign born, give country.).....

.....

What is your name *in full* (including your full middle name):.....

What was the date of your birth?.....

When and where were you naturalized? (For applicants of alien birth only).....

Are you married or single?.....Have you any minor children; if so, how many?.....

What is your height in inches?.....Your weight, in pounds?.....

Give the nature and dates of all serious sicknesses and injuries which you have suffered:.....

.....

If either parent, or brother, or sister has died, state cause and age in each case:.....

Do you use intoxicating liquors or narcotics; if so, to what extent?.....

Have you found your health or habits to interfere with your success in civil life?.....

What academy, high school, college, or university have you attended? State periods of attendance from year to year, and whether you were graduated, giving date or dates of graduation:.....

.....

Name any other educational advantage you have had, such as private tuition, foreign travel, etc.:.....

.....

Give all literary or scientific degrees you have taken, if any, names of institutions granting them, and dates:.....

With what ancient or modern languages or branches of science are you acquainted?.....

How many courses of lectures have you attended? Names of colleges and dates:.....

.....

When and where were you graduated in medicine?.....

(Fill this out and send it to the Surgeon General, U. S. Army, Washington, D. C.)

Have you been before a State Examining Board? If so, state when, where, and with what result:*.....

.....

Are you a member of any State medical society? If so, give its name.....

Have you had service in a hospital? If so, state where and in what capacity, giving inclusive dates of each kind of service: .....

What clinical experience have you had in dispensary or private practice?.....

.....

Have you paid particular attention to any specialty in medicine; if so, what branch?.....

What opportunities for instruction or practice in operative surgery have you had?.....

.....

Have you previously been an applicant for entry into the United States service? If so, state when, where, and with what result (if rejected, state why).....

Are you a member of the organized militia? If so, state with what organization and in what capacity:

.....

Have you been in the military or naval service of the United States as cadet or otherwise? If so, give inclusive dates of service with each organization, designating it.....

What occupation, if any, have you followed other than that of student or practitioner? .....

What is your present post-office address?.....

What is your permanent residence?.....

Signature.....

The correctness of all the statements made above was subscribed and sworn to by the applicant before me this.....day of.....A.D. 191

[SEAL] .....

*This application must be accompanied by a certificate from the proper official that the applicant is duly registered to practise medicine in the State in which he resides.

Form 149

New York, August 18, 1917.

THE CALL OF DUTY.

THE United States Army is still in great need of volunteers for the medical corps, not more than half of the number that will eventually be required having yet offered their services. This is no reproach to the medical profession of America, for it has already given of itself to our country in greater proportion than any other professional body; fully 10 per cent. of the practising physicians of service age have joined the forces, and are hard at work in the training camps or are even now on active service in France or helping to supply the deficiency in the military hospitals in England and other of the allied countries.

But of us much more than our share is demanded. The country needs 20 per cent. of its doctors between the ages of 25 and 55 years, and it must have them, at whatever sacrifice to their practice and their comfort. It will get them, and without the conscription which has been suggested as a possible eventuality, but naturally the process is a slow one. Domestic and social obligations cannot be put aside at a day's notice, and the man with a family must see to their provision before he can give himself to the cause. It is getting near the time, however, when this step must be taken, and the sooner now it is done the better. The process is a simple one; it is only necessary to fill out the application blank to be found on pages 287 and 288 of this issue of the MEDICAL RECORD and to send it to the Surgeon General, U. S. Army, Washington, D. C. The reply from the Surgeon General, with full directions regarding the next thing to be done, will be received in due time. Send in the application at the earliest possible moment, and when once it is sent be ready to accept your commission and act upon your orders as soon as they are received.

THE "PARESIS" OF GUY DE MAUPASSANT.

THE virus of syphilis is one poison which is not known to possess the power of stimulating vital processes in minute quantities. This should be due to the fact that it acts rather on the more primitive tissues than on the highly differentiated elements. In the cortical lesions of paresis there are plenty of evidences of cerebral excitation, euphoria, etc., but nothing which corresponds to a genuine increase of nervous force. Many writers, artists, and others possessing creative faculty, have become paretics, but so far as we know none ever did better work, or even average work, after the début of his disease.

In *L'Union Médicale du Canada* for July 1, Professor Le Sage endeavors to prove that Guy de Maupassant, born in 1850, was already in the grip of paresis in 1880, and that after this period he produced his masterpieces. For the next ten years his work showed a comparatively sane mind corresponding with his excellent physique. His heredity was poor, and as a young man he was neurasthenic, but served for a time in the Franco-German war. During the period 1871-1880 he wrote himself into success, artistic and personal. He was compared in love affairs to Don Juan. He abused eating and drinking, although his resort to narcotics seems to have been due at first to migraine. For this he tried everything—ether, morphine, chloral, etc. Later he did some of his work on these stimulants. Yet during this period he was, as a rule, happy in comparison with the succeeding decade. He had always shown a cyclothymic tendency, and as years advanced his periods of depression increased in frequency and duration. During these periods he felt a sense of helplessness and adverse fate. His sadness seems to have come to dominate his personality. He appears to have become obsessed by death, fear, and other painful concepts, much as was Poe.

Le Sage bases his paresis theory on pupillary anomalies, speech disturbances, and amnesia which developed midway in the 80's. A study of the evidence shows that this is scanty and inconclusive. He suffered severely from migraine, as did his mother, and these symptoms stood doubtless in relation to his migrainous periods. This affection became interwoven with his personality. When suffering he would answer queries as to his trouble by saying, "It is nothing; it is migraine." He, however, left some vivid accounts of his sufferings. At the close of this period—the 80's—he developed a spirit of litigation and marked hypochondria. His solicitude about the state of his various organs, his so-called autoscopic tendency, is certainly very unlike paresis. Hallucinations of special sense also developed. A paresis of the levator palpebrarum of the right side, a weakness of the writing arm, are regarded as suspicious by Le Sage, but these often go with severe migraine. Attacks of transient amaurosis were probably due to the teichopsia so often seen with migraine. De Maupassant himself blamed many of his symptoms on large doses of antipyrin taken for the head pains. Before his death, in 1893, he suffered a physical breakdown. His handwriting became much altered, showing the presence of language disturbances. He tried suicide, and, when interrupted, his strength was so great that three men were needed to hold him.

Death occurred in a sanatorium after a series of apoplectiform attacks.

Le Sage, by a somewhat artificial grouping of the symptoms, seeks to demonstrate that the case was from first to last paresis. Even the migraine was of specific origin. He infers that the victim wrote 27 volumes, including his masterpieces, while in the grip of paresis; and even that the very excellence and quality of the work were due to the disease. He believes that in the absence of his disease and of his abuse of alcohol, drugs, etc., his literary productions would have shown a marked contrast; that he would have shown optimism, different motivations, and greater delicacy.

We hardly think that any alienist would agree with this diagnosis of paresis, but the subject is of great interest because it could lead to some light on the possibility that in incipient paresis there is a period of actual increase of mental activity due to the stimulus of disease toxins. So far as we know, such a phase has never been recognized.

MORTALITY IN THE CITY OF LAS PALMAS.

An editorial notice which covered the presence of alcoholism and syphilis in Grand Canary Island was published recently in the Medical Record. In the same survey, which appeared serially in the *Gaceta Médica Catalana*, we read in the issue of May 31 an account of the mortality of Las Palmas during the period 1908-1911 inclusive. An opportunity is thereby afforded for a study of the probable influence of these race poisons on the Canarians. The population of the city is placed at about 64,000, and the death rate is seen to be between 17 and 18 per 1000 inhabitants, which is very favorable. The chief item of mortality is in the first two years of life. Deaths from congenital debility and vices of conformation number 299, while bowel troubles reach the sum of 543. Adding these figures, we obtain a total of 842 for four years, or 210 annually, from 5 to 6 per cent. of all deaths. Still births are not mentioned. In general, there is no means for computing the influence of the race poisons on infantile mortality. Pneumonia claims 111 victims annually, and pulmonary tuberculosis 93. Deaths from malignant tumors average about 30 annually, while 79 die every year from organic heart disease and 73 from "congestion, hemorrhage, and softening of the brain." Not readily intelligible are 68 annual deaths from "simple meningitis." Whether these figures affecting the heart and brain are high for a syphilitic and alcohol-ridden city must be left to the expert. Not a single death is set down outright to alcoholism, although 12 or 13 annual victims of syphilis are recognized. Aortitis, aneurysm, etc., may be concealed among "deaths from other causes," which in 1910 and 1911 averaged 75 a year.

There can be no doubt concerning the infrequency of certain organic diseases attributed to racial poisons, for cirrhosis of the liver claims but 7 or 8 victims annually, and nephritis in all its forms but 21. In the years 1910-1911 there were but 6 suicides, and during the same period 26 "violent deaths." As no fatal accidents are mentioned, we infer that such items are placed under the latter heading. The low incidence of infectious diseases is worthy of mention. Typhoid claims about 21 victims annually and diphtheria 16 to 17. Pertussis occurs apparently only in epidemics—in 3 of the 4 years there were no deaths from this cause. Grippe and malaria are almost unknown as causes of death, and there was no smallpox during this period. In 1911 there were 23 deaths from puerperal sepsis.

All in all, we must conclude that Las Palmas is a fairly healthy city, much more so, in fact, than the majority of towns in its latitude. The figures make us somewhat skeptical as to the ravages of alcohol and syphilis, which no doubt prevail largely among the floating population. In the one item of tuberculosis, especially, the latter must also be borne in mind, to say nothing of other chronic maladies, for Las Palmas has always been known as a health resort.

The Football Problem in Brazil.

In the temperate regions of the North, the football problem deals chiefly with the death and disability which follow in the wake of the game. In Brazil, on the contrary, the problem deals with the possible danger from muscular overstrain in the undeveloped youth (before the age of 18). The medical literature on the subject is extensive, and the doctors take sides on the subject. In the *Brazil-Medico* for April 28, Autran dwells on the rapid generation of fatigue toxins and their possible deleterious action on the growing organism. Metabolism may be greatly disordered, in that excessive combustion deprives the subject of reserve protein, so that he is less able to fight disease. Metabolism in a growing boy differs necessarily from that of the adult. Assimilation is a function superior to disassimilation. That which should serve for growth and nutrition—for assimilation, in other words—is burned up with poisonous by-products and lessened reserves. This special problem does not exist in the North, because football is but one of a number of violent sports, many of which are not played much in Brazil. The same reasoning would apply to cross-country running, lacrosse, rowing, etc. The viewpoint of the author seems entirely theoretical. He uses many neat expressions, such as the "passing of physiological into pathological fatigue," but does not cite a single fact to bear out any of his contentions. He lays down the maxim that from 13 to 18 the boy's exercises should be limited to formal gymnastics. After that period he may engage in football "in moderation" and "within physiological limits."

The Founder of Serotherapy.

The death of Behring appears to have started a mild controversy over the actual founder of serotherapy. It has usually been accepted that Behring had no competitor for this claim, with the possible exception of Roux. But in the *Gaceta Médica Catalana* for May 31 Chabás attempts to show that

Ferrán, the Spanish bacteriologist, is entitled to the honor. As early as 1884 he discovered his anti-cholera serum and began to employ it experimentally and therapeutically. In 1892, considerably in advance of the period of introduction of diphtheria antitoxin, Ferrán received full credit for the paternity of the idea of serotherapy from German authorities. A brief review of that case shows quite clearly that Ferrán worked entirely on prophylactic lines, and that his serum from cholera convalescents was used to immunize healthy subjects. He therefore sought to use only natural immune bodies, which, of course, cannot be prepared at will. According to Chabás, however, Ferrán was active in other directions as a pioneer of serotherapy, so that his claims in that direction are more than justified. Thus he made more or less extensive researches in the production and use of vaccines or serums for the prevention and treatment of diphtheria, bubonic plague, typhoid and typhus fevers, and various other infectious diseases.

Diagnosis of Scabies by the General Practitioner.

Mild and mildest scabies is readily overlooked by the general practitioner. Severe cases, because of the coexistence of itching and contagious pustules, are often recognized, especially as they are apt to occur in certain social strata or groups. The diagnosis, however, is little better than a guess, as actual demonstration of burrows, ova, feces, and the tick itself, does not occur. Sabouraud, the distinguished dermatologist, writing in *La Presse Médicale* for June 21, makes it plain that the non-specialist must unlearn several beliefs or axioms which animate him. Scabies is not a venereal disease *per se*, although it is a "cubiculary" affection, hence incidentally venereal. The reason that it is a disease acquired from sleeping with others in beds is simple—the parasite is a night walker, or perhaps better evening walker. Itching is comparatively mild in the day time, and other methods of contagion, however numerous, are almost negligible in practice. Scabies is a disease of the younger portion of the populace. The infant and child and their elders share beds with others for economic reasons. Another maxim of the general practitioner is that history or evidence of contagion will clear up a diagnosis. So he asks, "Have you slept with some one who scratched?" This is practical, but with limitations. The victim may have contracted the disease by occupying a hotel bed after another guest, the sheets not having been changed in the interim. The general practitioner further believes much in certain localisations as hands and fingers, feet (in infants), penis, and female breast. But this distribution refers really to the draped figure. Strip the patient, and other localities will be not less in evidence, notably the axillæ and buttocks. The general practitioner further looks at the webs and insides of the fingers first, the specialist, on the other hand, guided by experience, first looks on the wrist folds. Hence it is not that the general practitioner must unlearn anything outright; he must only learn that his precepts are incomplete, and may cause him to miss a diagnosis now and then.

News of the Week.

New Hospital Plans.—Plans for a new building for the Knickerbocker Hospital, formerly known as the J. Hood Wright Hospital, have been filed. The new hospital will occupy the entire block front on the west side of Convent Avenue, between One Hundred and Thirtieth and One Hundred and Thirty-first Streets. The main building will be six stories in height and will cost approximately $350,000. It will contain 200 private rooms and ward rooms for the accommodation of an additional 200 patients.

Warning Against Court-Plaster.—The Department of Health of New York City has issued a warning against the use of any but standard grades of court-plaster. The research laboratories of the department have been making examinations of court-plaster, and while they have as yet found no germs of tetanus in most of the specimens, they believe a warning is justified. The public is particularly warned against the purchasing of small packages of court-plaster from street peddlers.

Nutrition Clinics.—The New York Health Department, following the lead of Dr. William P. Emerson of Boston, who has established a clinic for the treatment of cases of defective nutrition at the Massachusetts General Hospital, has established five clinics in New York City, which are intended mainly for the treatment and supervision of the large number of school children who have shown marked evidence of defective nutrition. A large part of the work of these clinics will be educational in nature. It is probable that classes of instruction modeled on the tuberculosis classes will be organized as a part of this work. These clinics will be held at Bellevue, Cornell, and the Post-Graduate hospitals and at Bowling Green, 98 Washington Street, and the Brooklyn Association for Improving the Condition of the Poor, 104 Livingston Street.

Health Department Will Appeal Patent Medicine Case.—In the case of a patent medicine interest against the New York City Health Department, the Appellate Division of the Supreme Court has declared invalid the so-called "formula disclosure ordinance." The principal argument advanced by the patent medicine interests was the claim of "taking private property without due process of law." The Health Department will appeal the case.

Major Joel E. Goldthwaite of Boston, who has been visiting the military hospitals of France and England for the purpose of studying methods of treating wounds, has returned to this country.

Dr. Thomas F. Erdman has tendered his resignation as superintendent of the Norwich (Conn.) Hospital for the Insane.

Memorial Hospital Planned.—Application for a charter is soon to be made for a hospital to be built as a memorial to Carson C. Peck, vice-president of the F. W. Woolworth Company and owner of the Brooklyn *Times*, who died about two years ago. The hospital is to occupy a site bounded by Albany and Troy Avenues and Crown and Montgomery Streets, Brooklyn, and is to be known as the Carson C. Peck Memorial Hospital.

In Honor of Dr. Santos Fernandez.—On July 24, the seventieth birthday of Dr. Juan Santos Fer-

nandez, the Cuban ophthalmologist, there was held in his honor at the Havana Academy of Sciences, a joint meeting of twenty-seven different medical and literary societies. The president of each society made an address eulogizing the life and labor of Dr. Santos Fernandez, and a gold medal and diploma were given to him, the diploma being signed by all the chairmen of the different associations. The presentation was made by Dr. Carlos de la Torre, and Dr. Juan Santos Fernandez made an address of thanks.

The Fourth Cuban Medical Congress.—The Fourth Cuban Medical Congress will be held on December 16-22. The membership of the Congress is over 650 and it is hoped to raise it to more than 1,000. The Congress will have eight sections. The executive committee is composed as follows: *President*, Dr. Aristides Agramonte; *Vice-Presidents*, Drs. José A. Presno, Jorge Le Roy; G. Fernandez Abreu, Francisco Etchegoyen, M. Weiss, José A. Clark, A. Garcia Rivera, Manuel Altuna; *Secretary*, Dr. Francisco M. Fernandez; *Vice-Secretaries*, Drs. Julio Carrerá, Enrique Casuso, Ramiro Carbonell; L. F. Rodriguez Molina; *Treasurer*, Dr. José P. Alacán. The official subjects to be discussed are: "Arterial Tension"; "On Gastro-Intestinal Disturbances of Infancy;" "Gunshot Wounds of the Abdomen;" Gastro-Enterostomy in Gastric Ulcer;" "Obstetric Analgesia;" "School Hygiene in Cuba;" "Statistics on Mortality and Public Health;" "Composition of the Blood, Its Changes in Cuba;" "The Present Status of Cataract Operation;" "Conservative Surgery in Carcinoma of the Larynx;" "Relations Between the Mouth and the General Health;" "Can the Pharmacist Refuse to Dispense Any Prescription?" "Modifications Needed in the Inspection of Meats." Ten prizes are offered for competition on different subjects, pertaining chiefly to tropical matters. The executive committee, through the MEDICAL RECORD, is pleased to extend an invitation to any American doctors who may be able to visit Cuba during the time mentioned, to attend all the sessions and social meetings as guests of the Congress.

Specific Antipoliomyelitis Serum for Clinical Testing.—Dr. Horace Greeley, 140 Clinton Street, Brooklyn, N. Y., offers free of charge to the profession for clinical testing a limited amount of horse-serum from an animal immunized with cultures of five strains of the poliomyelitis organism obtained from the nerve centers of victims of last year's outbreak. The serum has been prepared with the same technique as is employed in the production of anti-meningococcus serum, so successfully used in cases of cerebrospinal meningitis, and it is hoped will prove effective in reducing the mortality and extent of paralysis in poliomyelitis. The serum will be supplied in vials of 25 c.c. and should be used on the day obtained, intraspinally. It is expected that full data regarding the course of a case, in which the serum is used, will be supplied. When desiring serum, a physician should either send a written request or call in person. Information in regard to cultures used in the preparation of the serum will be found in articles by Dr. Greeley published in the MEDICAL RECORD, January 13, 1917; *Journal of Laboratory and Clinical Medicine*, July, 1917; *Boston Medical and Surgical Journal*, April 12, 1917; *Long Island Medical Journal*, April, 1917; *Northwest Medicine*, May, 1917; *Southern Medical Journal*, August, 1917.

Licenses to Practice Medicine in Alabama.—Thirty-two out of forty-four applicants for medical licenses, who recently took the State Board examinations, have received licenses to practise medicine in Alabama.

Dysentery Epidemic in Germany.—A special cablegram to the New York *Sun* is authority for the statement that there is an epidemic of dysentery in Iserlohm, in the Rhenish Westphalian region. Several deaths are reported and many persons are ill. In Duisberg it is said that out of 292 cases there were 20 deaths. Similar reports published in Berlin declare that the dysentery rate in Berlin has reached a figure hitherto unknown. The prevalence of the disease is attributed to the shortage of food which leads people to eat doubtful substances.

Typhoid Among Interned Germans.—Two cases of typhoid fever have been reported among the interned German sailors at Gallop's Island, in Boston Harbor. The affected men have been removed to the marine hospital at Chelsea, 270 other Germans at the island have been inoculated against the disease, and all visiting privileges have been cancelled.

Salvarsan Bill Set Aside.—The Senate Patents Committee has decided to defer action on bills to commandeer German patents for the manufacture in this country of salvarsan.

Obituary Notes.—Dr. MICHAEL R. LADEN of Hartford, Conn., died on August 2, at St. Francis Hospital, as the result of being overcome by the heat. He was 47 years of age and was a graduate of New York University, in 1898.

Dr. HARRY WALLACE HASKELL, a graduate of New York University Medical College, in 1891, for twenty-five years a practising physician of Brooklyn, died at the home of his sister in that city, July 28, aged 52 years.

Dr. ELBERT CLARENCE DRAKE, a retired physician of Brooklyn, died August 2, at the age of 70 years.

Dr. WALTER D. GREENE, a graduate of the University of Buffalo, in 1876, died suddenly in Buffalo, N. Y., August 4, aged 64 years. He was formerly a resident of Starksboro, Vt., and for some years connected with the Board of Health of Buffalo.

Dr. THOMAS W. HANNON, a graduate of Bellevue Hospital Medical College, in 1891, died at his home in Hoosick Falls, Vt., August 1, aged 55 years.

Dr. THOMAS A. CHAPELL, retired, died in Jacksonville, Fla., from apoplexy, on July 29, aged 72 years. He formerly practiced his profession in Macon, Ga.

Dr. WARREN A. MAXFIELD, a graduate of Rush Medical College, in 1897, died at his home in Hudsonville, Mich., on July 31, aged 46 years.

Dr. JOHN B. DONNELLY, of Gardner, Mass., died of acute nephritis after an illness of several years, on August 2, aged 60 years. He was a graduate of Harvard University Medical College, in 1893 and formerly chief surgeon at the Henry Heywood Memorial Hospital.

Dr. CHARLES BOYD KELSEY died at his home in New York City, after a year's illness, on August 4, aged 67 years. He was a graduate of the College of Physicians and Surgeons, in 1873, and a member of the American Academy of Medicine. He was one of the first surgeons in this country to make a

specialty of rectal diseases, and for many years, until his health failed, was a practitioner and authority in proctological affections.

Dr. JAMES HENDERSON died of tuberculosis at the home of his parents in Toronto, Canada, on July 17. He was a graduate of Toronto University, in 1900. He formerly practiced medicine in Sudbury and Regina, Sask., and served in South Africa with the Canadian forces and with the expeditionary force at Kut-el-Amara in the present war.

Dr. HENRY EDWARD WAITE, a graduate of the Eclectic Medical College of the City of New York, a manufacturer of electrical apparatus, died at his summer home in Bethel Park, N. Y., July 26, aged 71 years. Dr. Waite formerly practiced medicine in Bridgeport, Conn., but moved to New York twenty-five years ago.

Dr. WILLIAM IZARD BULL, a graduate of the Medical College of South Carolina, and a surgeon in the Confederate Army during the Civil War, died at his home in Charleston, S. C., on July 29, aged 80 years.

Dr. ROBERT H. CARTER, a graduate of Louisville Medical College, in 1874, died at his home in Lynnville, Tenn., July 29, aged 70 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE RED CROSS AND THE ORDER OF ST. JOHN—THE LORD ROBERTS MEMORIAL WORKSHOP—GERMAN LOSSES.

LONDON, July 21, 1917.

THE Red Cross Society's organization is well up to date, as is also that of the Order of St. John. This is clear from a summary of work in Egypt, which has reached the headquarters of the joint war committee. Red Cross stores and comforts are now being delivered by the aerial service. An aeroplane leaves a point in the canal zone daily and carries such Red Cross comforts as fans, fly whisks, chocolate, gramophones, etc., to outlying medical units in the desert.

The memory of Lord Roberts is being appropriately honored to-day. On the suggestion of Lord Cheylesmore, contributions to the Lord Roberts memorial workshops are being added to. They provide training and employment for soldiers and sailors disabled in the war, and are of a scope which is continually extending. The craftsmanship practised in them is of high technical excellence and easily competes with trade productions. It is further of special interest as the production of heroes, many of whom have fallen under almost hopeless disabilities and apart from the assistance thus provided might have sunk into neglect and poverty. Not only do they become self-supporting individually, but the workshops quickly reach the stage when building and equipment suited to the use of maimed workmen are provided. This work well reflects Earl Roberts' practical sympathy with his men by whom he was always idolized.

To-day we are holding a collection in London and emblems are being sold by ladies; the emblems, which number seven millions, are in charge of Lady Warrender and a council. A garden fête is being held in Belgravia to-day in support of the movement, and to-morrow a silent tribute is to be given throughout the nation.

The awful ravages of war are illustrated by a computation of the German losses last year. At the end of 1916 Germany is said to have had a force of five and a half millions of all ranks, but not counting recruits. In the latter part of 1916 the Higher Command formed about 100 new battalions—not altogether fresh troops.

They were raised in different ways; in some districts a company of full war strength was formed of the ersatz (or replacing) battalion, and these were collected together to form new regiments—a regiment representing three battalions equal in full war strength to three thousand men. Some battalions were formed by taking a company from every infantry regiment in a great number of divisions, but these companies were often replaced by drafts from home depots. About thirty new divisions were thus raised by the end of 1916. The German system of recruiting before the war must be considered: By the law every male from 17 to 45 was liable for service in the active army, but his service did not actually begin until he was 20. At that age, if declared fit, he was passed to the depot of the unit to which he had been allotted. Thus a man born in March, 1894, was called a man of the 1914 class. The Germans began the war with their men of the 1913 class, 21 years old. In the years 1911, 1912, and 1913 the classes called up for service in the active army were respectively 563,024, 587,608, 587,888. But these do not represent all that were fit. Fifteen per cent. of the whole were pronounced fit, but were not required, and were posted to the reserve. Twenty-five per cent. were declared temporarily unfit and were put back for reexamination next year. Ten per cent. were said to be totally unfit and were excused from service. Of the three categories, if we take an average of 20 per cent., to represent those who under the stress of war could be called to the colors, it is possible to calculate the number of men who were called in 1914, 1915 and 1916. Allowances must be made for men called back for munitions, railway, and necessary home service work. Since the beginning of the war the Germans have put into the line the 1914, 1915, 1916, 1917, and some portions of 1918 classes, and they have called up a part of the 1919 class to the depots.
